FOREWORD

This Proceedings documents the talks, posters, tutorials, and symposia presented at the 24th Annual Meeting of the Cognitive Science Society. The meeting took place at George Mason University in Fairfax Virginia, USA from August 7 through August 10, 2002. Hundreds of submissions were received from around the world. Following last year's first European conference, it seems as if the annual meeting has become a truly international event.

The theme of this year's conference was Applied Cognition; that is, cognitive science that is either inspired by or applied to real world problems. This theme was reinforced by our plenary speakers. Stuart Card (of PARC) reminded us that successful applications of other sciences did not take a direct route from the science to application, but required the development of engineering disciplines that entailed their own research, paradigms, and formalisms. David Woods (of The Ohio State University) proposed an outline for the form that one such cognitive science-inspired engineering discipline might take. As co-Chairs, we limited our direct manipulation of the Program to our selection of these two plenary speakers. However, we are pleased to note that a large number of symposia, talks, and posters seem to have been inspired by or contributed to applied issues.

This year saw the introduction of a new submission category: publication-based submissions. Publication-based submissions allow established researchers to present talks in their area of expertise without submitting full 6-page papers. Instead, the researcher submits proof of a publication record in a given area along with a 500-word abstract of the work they would like to present at the conference. A one-page camera-ready abstract, similar to the member abstracts, is submitted later and is included in the proceedings. The goal of this new submission category is to encourage greater participation in the conference by senior cognitive scientists. Judging by the success of this category at CogSci2002, we expect it to grow over the coming years.

Like the Chairs who have gone before us, we too felt almost overwhelmed by the task of selecting and organizing our multitude of papers and symposium into coherent and non-conflicting sessions. Our task was made both easier and harder this year by the use of Simon™, conference management software commissioned by the Cognitive Science Society. Future Chairs will greatly benefit from our alpha testing of this potentially marvelous software.

There are many people to whom we owe thanks and we hope that we have listed each of their names on the pages that follow this Foreword. We would like to provide our special thanks to the following:

The Governing Board of the Cognitive Science Society for inviting us to host the meeting.

The Program Committee for acting in the capacity of Associate Editors in managing the review process.

The more than 200 reviewers for providing professional reviews and, in most cases, copious comments.

Frank Ritter and Chris Kello for organizing and coordinating the tutorial program.

Mike Byrne and Kevin Gluck for organizing the student volunteers.

Stellan Ohlsson for chairing the Marr Prize committee.

Debbie Kranz for being ready, willing, and able to coordinate the local arrangements.

Art Markman and Deborah Gruber for introducing a central Cognitive Science Society presence to the conference.

Financial support: Air Force Office of Scientific Research, DARPA, Air Force Research Labs, CHI Systems, Aptima and The Robert J. Glushko and Pamela Samuelson Foundation. George Mason University donated the use of the facilities and backed the conference with substantial financial contributions from the College of Arts & Sciences, School of Education, School of Information Technology & Engineering, Provost Office, and Psychology Department.

The plenary speakers: Stu Card and David Woods.

And our authors, symposium participants, and attendees for making the conference a true intellectual feast.

Wayne D. Gray & Christian Schunn
Conference Chairs, CogSci2002

About the Society

The Society is a non-profit professional organization, and its main activities are sponsoring an annual conference, publishing the journal *Cognitive Science*, and promoting research interactions across traditional disciplinary boundaries. The Society was incorporated as a non-profit professional organization in Massachusetts in 1979.

The Cognitive Science Society, Inc. brings together researchers from many fields that hold a common goal: understanding the nature of the human mind. The Society promotes scientific interchange among researchers in disciplines comprising the field of Cognitive Science, including Artificial Intelligence, Linguistics, Anthropology, Psychology, Neuroscience, Philosophy, and Education.

Tutorial Co-Chairs

Frank E. Ritter (Penn State)

Chris Kello (George Mason University)

Local arrangements Chair: Chris Kello (George Mason University)

Tutorial Committee Members

Randolph M. Jones (Colby College and Soar Technology)

Todd Johnson (University of Texas/Houston)

Kevin Korb (Monash, Aus)

Michail Lagoudakis (Duke)

Josef Nerb (Freiburg)

Gary Jones (Derby)

Padraic Monaghan (Edinburgh)

Richard Young (Hertfordshire)

Contents

Rumelhart Prize Talk

Bayesian Modeling of Memory and Perception	9
<i>Richard M. Shiffrin (Indiana University)</i>	

Rumelhart Symposium

Rumelhart Symposium: Honoring Richard Shiffrin.....	11
<i>Susan Dumais (Microsoft Corporation)</i>	
<i>Wilson S. Geisler (University of Texas)</i>	
<i>Jeroen Raaijmakers (University of Amsterdam)</i>	
<i>Mark Steyvers (University of California)</i>	

Plenary

Cognitive Science as the Engine of Innovation: Beyond Human-Computer Interaction	13
<i>Stuart Card (Information Sciences and Technologies Laboratory, Xerox PARC)</i>	
Steering the Reverberations of Technology Change on Fields of Practice: Laws that Govern Cognitive Work.....	14
<i>David D. Woods (Institute for Ergonomics, The Ohio State University)</i>	

Symposium

The Cognition of Complex Visualizations	18
<i>J. Gregory Trafton (Naval Research Laboratory)</i>	
<i>Priti Shah (University of Michigan)</i>	
<i>Eric G. Freedman (University of Michigan)</i>	
<i>Susan Kirschenbaum (Naval Undersea Warfare Center)</i>	
<i>Peter C-H.Cheng (University of Nottingham)</i>	
<i>Discussant: Mary Hegart (University of California, Santa Barbara)</i>	
Nature's Turing Test	20
<i>Organizer: Thomas R. Zentall (University of Kentucky)</i>	
<i>Participants:</i>	
<i>Perceptual Classes: Edward A. Wasserman (The University of Iowa)</i>	
<i>Superordinate Classes: Thomas R. Zentall (University of Kentucky)</i>	
<i>Relational Classes: Roger K. R. Thompson, Mary Jo Rattermann, and Anthony P. Chemero (Franklin & Marshall College)</i>	

The AMBR Model Comparison Project: Round III — Modeling Category Learning	21
<i>Organizers: Kevin A. Gluck (Air Force Research Laboratory) and Richard W. Pew (BBN Technologies)</i>	
<i>Participants:</i>	
<i>Experiment Design and Comparison of Human and Model Data: David Diller and Yvette Tenney (BBN Technologies)</i>	
<i>An EPIC-Soar Model of Concurrent Performance on a Category Learning and a Simplified ATC Task: Ron S. Chong (George Mason University) and Robert E. Wray (Soar Technology, Inc.)</i>	
<i>Developing Concept Learning Capabilities in the COGNET/iGEN Integrative Architecture and Associated AMBR ATC Model: Wayne Zachary (CHI Systems, Inc.)</i>	
<i>An Activation-based Theory of Categorization: Christian Lebiere (Carnegie Mellon University)</i>	
<i>Concept Learning: Knowing and Reasoning in the DCOG Architecture: Robert G. Eggleston, Air Force Research Laboratory and Katherine L. McCreight, N-Space Analysis</i>	
<i>Symposium Discussant: Bradley C. Love (University of Texas)</i>	
 Inquiry, Technology, and Cognition: Theory and Practice	 23
<i>Organizer: Sarah K. Brem (Arizona State University)</i>	
<i>Participants:</i>	
<i>Technical and social supports for epistemic practices of scientific argumentation: William Sandoval, Kelli Millwood (UCLA) and Marie Bienkowski, Valerie Crawford (SRI International)</i>	
<i>Promoting critical inquiry from Web sources: Jennifer Wiley, Susan R. Goldman (UIC) and Arthur C. Graesser (University of Memphis)</i>	
<i>Tools for representational guidance during classroom scientific inquiry: Eva E. Toth (Allegheny-Singer Research Institute)</i>	
<i>Alternate forms of inquiry and their implications for theory and practice: Sarah K. Brem (Arizona State University)</i>	
 New Models of Connectionist Language Acquisition.....	 24
<i>Organizers: Ping Li (University of Richmond) and Brian MacWhinney (Carnegie Mellon University)</i>	
<i>Participants:</i>	
<i>Going beyond the input: the problem of generalization from sparse data: Jeff Elman</i>	
<i>The origin of categorical representation of language in the brain: Ping Li, Igor Farkas and Brian MacWhinney</i>	
<i>Acquisition of crisp and fuzzy concepts: Thomas Shultz</i>	

Publication-based Talks

Coordination of Talk & Action	26
<i>Richard Alterman, Alex Feinman, Seth Landsman and Josh Introne (Brandeis University)</i>	
Developing and Validating Cockpit Interventions based on Cognitive Modeling	27
<i>Deborah A. Boehm-Davis, Robert W. Holt, Melanie Diez and Jeffrey T. Hansberger (George Mason University)</i>	
The Information-Processing Function of Conscious Intentions	28
<i>Richard A. Carlson, Lisa M. Stevenson, Marios N. Avraamides and Daniel N. Cassenti (Penn State University)</i>	
Activity Awareness in Computer-supported Collaborations	29
<i>John M. Carroll (Virginia Tech)</i>	
Testing the Roles of Design History and Affordances in the HIPE Theory of Function	30
<i>Sergio E. Chaigneau (Universidad de Tarapaca) and Lawrence W. Barsalou (Emory University)</i>	
Misrepresenting Emergent Causal Processes as Non-Emergent: A Potential Schema for Overcoming Misunderstandings in Science	31
<i>Micheline T. H. Chi (University of Pittsburgh)</i>	
Protocol Evidence On Thought Experiments Used By Experts	32
<i>John J. Clement (University of Massachusetts)</i>	
Putting Geometry and Function Together — Towards a Psychologically-Plausible Computational Model for Spatial Language Comprehension	33
<i>Kenny R. Coventry, Angelo Cangelosi, Dan Joyce and Lynn V. Richards (University of Plymouth)</i>	
A Basis for a Rigorous Cognitive Science: Maintaining Context for Information Exchange between Modules in a Functional Hierarchy	34
<i>L. Andrew Coward (Murdoch University)</i>	
Dynamic Interrelations Among Processing Efficiency, Working Memory, and Problem Solving: A Longitudinal Study	35
<i>Andreas Demetriou (University of Cyprus)</i>	
Tutoring Real-Time Dynamic Task Performance: Using ADAPT to Augment Pilot Skill Acquisition	36
<i>Stephanie M. Doane and Daniel W. Carruth (Mississippi State University)</i>	

Implementing Latent Semantic Analysis in Learning Environments with Conversational Agents and Tutorial Dialog	37
<i>Arthur C. Graesser, Xiangen Hu, Brent A. Olde, Matthew Ventura, Andrew Olney, Max Louwerse and Donald R. Franceschetti (University of Memphis) and Natalie Person (Rhodes College)</i>	
Human-Automation Interaction Strategies.....	38
<i>Stephanie Guerlain (University of Virginia)</i>	
Statistical learning, implicit memory, and phonology.....	39
<i>Prahlad Gupta and John Lipinski (University of Iowa)</i>	
Mental Visualizations and External Visualizations.....	40
<i>Mary Hegarty (University of California)</i>	
Modeling aviation crew interaction using a cognitive architecture.....	41
<i>Robert W. Holt, Jeffrey T. Hansberger, Ronald S. Chong and Deborah A. Boehm-Davis (George Mason University)</i>	
Promoting Transfer through Case-Based Reasoning: Rituals and Practices in the Learning by Design Classroom and Evidence of Transfer	42
<i>Janet L. Kolodner (Georgia Institute of Technology)</i>	
Dynamic Adaptation to Critical Care Medical Environment: Error Recovery as Cognitive Activity	43
<i>Tate T. Kubose, Vimla L. Patel and Desmond Jordan (Columbia University)</i>	
Applications of Latent Semantic Analysis	44
<i>Thomas K Landauer (University of Colorado at Boulder)</i>	
Modeling the Development of Lexicon with DevLex: A Self-Organizing Neural Network Model of Lexical Acquisition	45
<i>Ping Li and Igor Farkas (University of Richmond)</i>	
Where Do Problem-Solving Strategies Come From?.....	46
<i>Marsha C. Lovett (Carnegie Mellon University)</i>	
Is There a Decision Bias For Information From Internally Consistent Sources?	47
<i>Shenghua Luan, Robert D. Sorkin and Jesse Itzkowitz (University of Florida)</i>	
Understanding and Scaffolding Constructive Collaboration.....	48
<i>Naomi Miyake and Hajime Shirouzu (Chukyo University)</i>	
Learning from Worked-Out Examples via Self-Explanations: How it Can(not) be Fostered	49

Multiple Perspectives on Consciousness for Cognitive Science

Richard A. Carlson (racarlson@psu.edu)
Department of Psychology, Penn State University
613 Moore Building, University Park, PA 16802 USA

The huge contemporary literature on consciousness spans multiple disciplines, including psychology, philosophy, and neuroscience. This tutorial will introduce participants to major proposals about consciousness, and their empirical and methodological implications. The goal is to prepare participants to explore the consciousness literature in greater depth.

Our consideration of perspectives on consciousness will be organized by considering how these perspectives address core questions about consciousness, including: (a) How can *subjectivity* and *agency* be accommodated in a scientific theory of consciousness? (b) How can *conscious* and *nonconscious* or *unconscious* processes and representations be systematically distinguished? (c) How can conscious mental states be assessed or measured? (d) How can dissociations and impairments of consciousness be understood? The literatures to be considered address these questions in analytic, functional, computational, and implementational terms.

Philosophical Perspectives

Philosophers approach the problem of consciousness from a variety of analytic perspectives, some focusing on contemporary formulations of the mind-body problem and others on analyses of subjective experience. Among the philosophical perspectives we will consider are John Searle's (1992) analysis of consciousness in terms of intentionality, David Chalmers's (1996) distinction between "easy" and "hard" problems of consciousness, David Rosenthal's (1993) "higher order thought" proposal, and Daniel Dennett's (1991) "multiple drafts" theory of consciousness.

Neuroscience Perspectives

Neuroscientists have made a wide variety of proposals concerning the neural correlates of consciousness (NCC). A starting assumption is that a subset of current neural activity is correlated with current conscious experience. There is controversy, however, concerning how that subset is to be identified. For example, the NCC might be limited to particular types of cells or anatomical structures, or comprise global patterns of synchronized neural activity. We will consider recent proposals concerning NCC by Crick and Koch (1998), Damasio (2000), and Edelman and Tononi (2000).

Psychological Perspectives

Psychological perspectives on consciousness generally focus on functionally-defined aspects of cognition. For

example, psychologists have identified consciousness with working memory (Baars, 1988), attention (Schneider & Pimm-Smith, 1997), metacognition (Nelson, 1996), and with the structure of mental states (Carlson, 1997). Cognitive research often focuses on distinguishing conscious and nonconscious influences on psychological processes such as learning (Dienes & Berry, 1997) and perception (Merikle, Smilek, & Eastwood, 2001). This research has generated a rich literature on methods for assessing consciousness.

APEX/CPM-GOMS: Modeling Human Performance in Applied HCI Domains

Half-day tutorial (morning)

Johnson Center/Enterprise

Roger Remington
NASA Ames Research Center
Moffett Field, CA 94035
mfreed@arc.nasa.gov

Bonnie John - Carnegie Mellon University

Michael Matessa - NASA Ames Research Center

Alonso Vera - NASA Ames Research Center

Michael Freed- NASA Ames Research Center

This tutorial introduces participants to CPM-GOMS modeling using APEX, a tool for applied human performance modeling. APEX-CPM is intended to be of value to both cognitive science researchers and HCI professionals. It is also valuable for teaching students about task-analysis, user-modeling, and computational cognitive modeling in general. The tutorial will teach participants how to represent GOMS, KLM, and CPM-GOMS task analyses in APEX-CPM, and to refine models based on output in the form of automatically generated PERT charts. We will also discuss recent improvements aimed at making it practical to model in more complex HCI domains. These include capabilities that (a) facilitate representation of simulation environments and (b) allow modelers to draw on a set of reusable building blocks both for cognitive/task modeling and for physical environment modeling. The tutorial will primarily consist of a guided tour through activities supplemented with presentations. Participants will work in pairs, supervised by at least four presenters, on applied modeling problems. This tutorial should be of particular value to people interested in developing, using, and/or teaching engineering models of human performance in HCI contexts. Some background in cognitive modeling and computer programming is recommended. Tutorial participants will be given a CD containing the APEX-CPM code, a world-building tool-kit, and a number worked example models.

Roger Remington is a Senior Research Psychologist at NASA Ames Research Center. He holds a Ph.D. in Psychology from the University of Oregon.

Bonnie John is an Associate Professor in the Institute of Human-Computer Interaction and Carnegie-Mellon University. She holds a Ph.D. in Psychology from Carnegie Mellon University.

Michael Matessa is a Research Psychologist at NASA Ames Research Center. He holds a Ph.D. in Cognitive Psychology from Carnegie Mellon University.

Alonso Vera is a Research Scientist at NASA Ames Research Center. He holds a Ph.D. in Experimental Psychology from Cornell University.

Michael Freed is a Research Scientist at NASA Ames Research Center. He holds a Ph.D. in Computer Science from Northwestern University.

How to Build Intelligent Interactive Agents Using Soar

Randolph M. Jones

Soar Technology, Inc., and Colby College

rjones@soartech.com

Robert E. Wray, III, Soar Technology, Inc.

Amy E. Henninger, Soar Technology, Inc.

Scott Wood, Soar Technology, Inc.

Ronald S. Chong, George Mason University

Soar has been under development for over two decades as an architecture for building intelligent systems and human behavior models. Recent research and development activity with Soar has emphasized building competent, autonomous agents that interact with realistic and complex simulated environments. This tutorial will teach some of the methods that we use to design and engineer such behavior models. Instead of focusing on strict cognitive modeling, this tutorial will discuss the complexities that autonomous behavior and real-time interaction impose on a model. It will not involve intensive programming of intelligent agents, but will concentrate on higher level issues of task analysis, knowledge representation, process-oriented modeling, and knowledge acquisition. Many of these activities are useful to learn even if one does not use Soar to implement models, but the tutorial will also demonstrate the ways that Soar approaches and informs (and sometimes exacerbates) these tasks. To this end, tutorial participants will study and tweak a variety of interactive behavior models, and learn techniques for representing knowledge and behavior in Soar. They will also gain experience with some of the new development tools that support Soar modeling. Tutorial participants do not need an extensive background in programming.

Presenters: Each of the presenters has research and industry experience building interactive intelligent agent systems. Many of these have been "believable" agents with large amounts of knowledge developed within Soar. Soar Technology, Inc., uses Soar and other software paradigms to create intelligent and usable software for a variety of defense applications. All of the presenters also have experience developing interactive models of human behavior for various purposes, such as improving intelligent agents, improving human-computer interaction, understanding learning in problem solving, and studying human error in interactive tasks.

ACT-R

Christian Lebiere
Carnegie-Mellon University

ACT-R is a cognitive theory and simulation system for developing cognitive models. It assumes cognition emerges through the interaction of a procedural memory of productions with a declarative memory of chunks and independent modules for external perception and actions. The ACT-R 4.0 version of the theory was detailed in the book "The Atomic Components of Thought" by John R. Anderson and Christian Lebiere, published in 1998 by Lawrence Erlbaum. Since its release in 1997, ACT-R 4.0 has supported the development of over 100 cognitive models published in the literature by many different researchers. These models cover topics as diverse as driving behavior, implicit memory, learning backgammon, metaphor processing, and emotion. We have recently developed a new version, ACT-R 5.0 that extends ACT-R 4.0 to be more interruptible, to achieve greater across-task parameter consistency, to have better mechanisms of production learning, and to be more in correspondence with our knowledge of brain function. While the new system extends the capabilities of ACT-R 4.0, it involves relatively few changes and is actually simpler. This short tutorial will provide an overview of ACT-R, as it is specified in the 5.0 version, and some of its applications. It will not assume a prior background in ACT-R 4.0.

Christian Lebiere is a Research Scientist in the Human-Computer Interaction Institute at Carnegie-Mellon University. He received his B.S. in Computer Science from the University of Liege (Belgium) and his M.S. and Ph.D. from the School of Computer Science at Carnegie Mellon University. During his graduate career, he worked on the development of connectionist models, including the Cascade-Correlation neural network learning algorithm. Since 1990, he has worked on the development of the ACT-R hybrid cognitive architecture and is co-author with John R. Anderson of the 1998 book "The Atomic Components of Thought". His main research interest is cognitive architectures and their applications to psychology, artificial intelligence, human-computer interaction, decision-making, game theory, and computer-generated forces.

Functional Imaging of the Brain -- Developing a Synergy of Cognitive Neuroscience Behavior and Modeling

Walter Schneider
University of Pittsburgh
Pittsburgh 152260
wws@pitt.edu

The last ten years have produced an explosive growth in brain imaging technology and findings. The combination of MRI, ERP, DTI, and PET enable non-invasive research on humans obtaining millimeter and millisecond resolution of activation, connection tracing, and mapping of transmitter systems. This large effort (1000+ papers per year) is providing detailed data of the biology of cognition and having a large impact on the conceptualization of cognitive science. There is a "grand challenge" to the field to relate the biology and mechanisms of human thought. There is a critical need for comprehensive behavioral, theoretical, and modeling efforts to interpret the findings. This tutorial will provide an introduction to the brain imaging methods stressing both the potential and limitations of the existing methods. We will describe the challenges that cognitive science methods may be particularly beneficial to resolving. We will look at efforts to relate modeling (e.g., ACTR, LSA) and activation data. We will provide guidelines on how to get into brain imaging via collaboration or direct imaging.

Walter Schneider (B.A. Psychology, U. Illinois 1971; Ph.D. Psychology Indiana U. 1975). He is a fellow of the American Psychology Association and AAAS, is known for his classic work on automaticity and skill acquisition, published some of the first papers on fMRI in humans, and has developed software systems for empirical and brain imaging systems used in 2,000 laboratories. His current research focuses on brain imaging and modeling of learning, attention, and language processing and the modeling of skill acquisition and control/automatic processing. His web site is www.pitt.edu/~schlab/People/walt.htm

A Cognitive Approach to Designing Human Error Tolerant Interfaces

Scott D. Wood (swood@soartech.com)

Soar Technology, Inc.
3600 Green Court, Suite 600, Ann Arbor, MI 48105 USA

Mike Byrne (byrne@acm.org)

Psychology Department, Rice University
6100 Main Street, MS-25, Houston, TX 77005 USA

Human errors are inevitable, but some are more inevitable than others. Human error has been blamed for countless catastrophes (cf. Casey, 1993; Perrow, 1984), yet errors are often merely symptoms of much larger underlying design problems. Designing for human error is a major challenge for developers of safety-critical and mission-critical systems. Human error is of particular concern for banking, commerce, medicine, military and other systems where tasks are performed with high frequency, or where the consequences of mistakes are grave or costly. Most approaches to error-tolerant design use either general design guidelines or treat humans as just another error-prone system component. To make errors a little less inevitable, we must take a comprehensive, psychologically-based approach to human-error tolerant design.

The goals of this tutorial are to provide researchers with a better understanding of the underlying causes of human error and present practical techniques for applying psychology to human-error tolerant designs. This tutorial approaches error tolerant design from a cognitive perspective, focusing on practical techniques for improving your system's ability to deal with inherent human limitations. Participants will learn the basics of human error, how to classify error types, a framework for error tolerant design, how to deal with multiple aspects of error in design, and how to form a multilayered defense against error.

Understanding Human Error

Reason (1990) defines and discusses many aspects of human error and its psychological underpinnings. Although there are many questions remaining about the attentional mechanisms used by Reason to explain error occurrence, his work provides a starting point from which to study human error and error tolerant design. Reason's human error taxonomy is framed around Rasmussen's Skills-Rules-Knowledge (SRK) framework (1979). In addition to specific error types within each of the SRK levels, Reason also identifies two general forms of error, "similarity matching" and "frequency gambling", that pervade each of the levels. This leads to general rules for erroneous memory retrieval, such as, "If the correct item is not retrieved, then the most similar, frequently accessed item will be retrieved." Additional insight can be gleaned by mapping Reason's taxonomy unto a standard human information processing architecture, such as ACT-R, EPIC or Soar.

Understanding and categorizing human error can be done at many levels, depending on the focus of the study. Reason (1990) also describes different levels for classifying error instances as one of behavioral (observable actions, such as omitting a procedural step), contextual (within the context of the task, such as "failed to press the button"), or conceptual (relating to internal mechanisms, such as "failed to perceive warning label").

Designing Error-Tolerant Systems

Many error-tolerant design efforts rely on general design guidelines (e.g. Smith and Mosier, 1986). However these guidelines are often not used or misapplied because they are sometimes overly general or atheoretical in nature. Mayhew (1992), provides a more theoretical mapping of guidelines into motor, cognitive, and perceptual areas, but has no framework to comprehensively address human error.

An effective error-tolerant design must address multiple aspects of human error to build a comprehensive, multi-layered defense. These aspects include error prevention, reduction, detection, identification, and correction, resumption of normal activities, and failure mitigation. In this tutorial we will describe a framework for mapping between error taxonomies, cognitive architectures and design guidelines, and present a task-analytic technique for applying the framework in a practical way.

Understanding the psychological factors that affect these areas is essential for good design. Likewise, understanding practical implications of applied psychology may lead to further theoretical advances in the field.

Rumelhart Prize Talk

Bayesian Modeling of Memory and Perception

Richard M. Shiffrin

Abstract

I present a framework for modeling memory, retrieval, and perception, and their interactions. The models are inspired by Bayesian induction to determine optimal decisions, in the face of a memory system with inherently noisy storage and retrieval. The starting point for this work was the Retrieving Effectively from Memory (REM) model for episodic recognition (Shiffrin & Steyvers, 1997). The general framework describes: 1) the storage of episodic traces, the accumulation of these into knowledge (e.g. lexical/semantic traces in the case of words), and the changes in knowledge caused by learning; 2) the retrieval of information from episodic memory and general knowledge; 3) decisions concerning storage, retrieval and responding. I give examples of applications to episodic recognition, and cued and free recall, perceptual identification (naming, yes-no and forced choice), lexical decision, and long-term and short-term priming, and briefly consider extensions to episodic categorization and retrieval of content from general knowledge.

Mark Steyvers (msteyver@psych.stanford.edu)
Dept. of Cognitive Sciences, University of California
3151 Social Sciences Plaza, Irvine, CA 92697 USA

This symposium honors Rich Shiffrin's contributions to cognitive science. Four former students will present highlights of their current work shaped in various ways by their mentor.

Data-Driven Approaches to Information Access (Susan Dumais)

Several lines of research that are motivated by the practical problem of helping users find and manage information in external data sources, most notably computers, will be described. The application areas include: information retrieval, text categorization, and question answering. A common theme in all these efforts is the analysis of the statistical properties of words in large volumes of real world texts. Simple statistical analyses and machine learning algorithms are used to solve practical information access problems. In addition these same statistical properties of objects in the world constrain human performance. Thus solutions to practical problems can shed light on human knowledge representation and reasoning.

A Bayesian Approach to the Evolution of Perceptual Systems (W. S. Geisler and R. L. Diehl)

Perceptual and cognitive systems, including the developmental and learning mechanisms that shape them during the lifespan, are the result of evolution by natural selection. Yet historically most approaches to the study of perception and cognition acknowledge only implicitly the role of natural selection. We propose a Bayesian theoretical framework that makes explicit the relationship between the statistical properties of the environment, the evolving genome, and the design of perceptual and cognitive systems. The proposed framework grew out of recent applications of Bayesian statistical decision theory in perception and cognition and recent efforts to measure the statistical properties of natural environments; however, the Bayesian framework encompasses many of the most important insights of previous theoretical approaches in perception and cognition. We first summarize the formal Bayesian framework and show how it can be used to formulate and test specific hypotheses about the design of perceptual and

cognitive systems. We then describe the connections between the Bayesian framework and other theoretical approaches.

SAM as a General Theory for Memory (Jeroen G. W. Raaijmakers)

The SAM theory for memory retrieval will be briefly reviewed. We show how the theory (including the extension proposed by Mensink & Raaijmakers, 1988, 1989) may be used to provide a new model for spacing and repetition effects. The resulting model can be seen as a mathematical formulation of the Component-Levels theory proposed by Glenberg (1979). It is assumed that on a second presentation of an item information is added to an existing trace if the episodic memory image corresponding to that item is retrieved. If it is not retrieved, a new image is stored. It is shown that the model predicts many standard findings including findings that were thought to be inconsistent with the Component-Levels theory. This application demonstrates how SAM may be used to provide quantitative formulations for verbal theories, making it easier to examine the exact predictions of such theories.

Inferring Causal Structure from Intervention (Mark Steyvers)

Information about the structure of a causal system can come in the form of observational data - random samples of the system's autonomous behavior - or interventional data - samples conditioned on the particular values of one or more variables that have been experimentally manipulated. Here we study people's ability to infer causal structure from intervention, and to choose informative interventions on the basis of purely observational data. We develop computational models of how people infer causal structure from data and how they plan intervention experiments, based on the representational framework of causal Bayesian networks and the inferential principles of optimal Bayesian decision-making and maximizing expected information gain. These analyses suggest that people can make rational causal inferences, subject to certain processing constraints and representational assumptions that may vary across participants.

Plenary

Cognitive Science as the Engine of Innovation: Beyond Human-Computer Interaction

Stuart Card (card@parc.com)

Information Sciences and Technologies Laboratory, Xerox PARC
3333 Coyote Hill Road
Palo Alto, CA 94304 USA

Abstract

Successful sciences usually spawn successful applications and application disciplines; in fact, one is suspicious of a science that can't claim practical results. The naive view is that results from the science are "applied" to problems, as in an "applied cognitive psychology," for example. The truth is more complex in general and it is particularly more complex for cognitive science. New advances in technology are amplifying still further the human role of informavore and the need for cognitive engineering and invention of cognitive products and government activities. The ability to meet these is a test of a cognitive engineering discipline and of the supporting sciences themselves. I am going to suggest some principles for organizing both cognitive science and the practical innovation around it by reflecting on what we have learned about using cognitive psychology in human-computer interaction. I will use this analysis to suggest a set of initiatives now within reach of the cognitive science community.

About Stuart Card

Stuart Card is a Xerox Research Fellow and the manager of the User Interface Research group at the Xerox Palo Alto Research Center. With Allen Newell and Tom Moran from CMU, he founded an effort to develop models of human performance that could be used in information system design. His thesis at CMU was the first thesis specifically in the new specialty of human-computer interaction. His study of input devices led to the Fitt's Law characterization of the mouse and was an important factor leading to the mouse's commercial introduction.

He and his group have developed a number of theories of human-machine interaction, including the Model Human Processor, the GOMS theory of user interaction, and information foraging theory. They have developed new paradigms of human-machine interaction, including the Rooms workspace manager and the Information Visualizer. The work has resulted in nine Xerox products and the founding of Inxight Software, Inc.

Card is a co-author of the book, "The Psychology of Human-Computer Interaction", a co-editor of the book, "Human Performance Models for Computer-Aided Engineering", and has served on many editorial boards. He received his A.B. in Physics from Oberlin College and his Ph.D. in Psychology from Carnegie Mellon, where he pursued an interdisciplinary program in psychology, artificial intelligence, and computer science. His most recent book, "Readings in Information Visualization", co-written and edited with Jock Mackinlay and Ben Schneiderman, was published in January 1999.

Steering the Reverberations of Technology Change on Fields of Practice: Laws that Govern Cognitive Work

David D. Woods (woods.2@osu.edu)

Institute for Ergonomics
The Ohio State University
1971 Neil Ave
Columbus, OH 43210 USA

Now all scientific prediction consists in discovering in the data of the distant past and of the immediate past (which we incorrectly call the present), laws or formulae which apply also to the future, so that if we act in accordance with those laws our behavior will be appropriate to the future when it becomes the present.

Craik, 1947, p. 59

Abstract

Research on cognitive work in context has abstracted a set of common patterns about cognitive work and about the relationship of people and computers. I offer four families of Laws that Govern Cognitive Work plus Norbert's Contrast as a synthesis of these findings to guide future development of human-computer cooperation. These Laws are one prong of a general strategy to avoid repeats of past "automation surprises".

1. Patterns of Reverberations

Observational studies of cognitive work in context have built a body of work that describes how technology and organizational change transforms work in systems. Points of technology change push cycles of *transformation* and *adaptation* (e.g., Carroll's task-artifact cycle; Carroll and Rosson, 1992; Winograd and Flores, 1987; Flores, Graves, Hartfield, and Winograd, 1988). The review of the impact of new technology in one operational world effectively summarizes the general pattern (Cordesman and Wagner, 1996, p.25):

Much of the equipment deployed ... was designed to ease the burden on the operator, reduce fatigue, and simplify the tasks involved in operations. Instead, these advances were used to demand more from the operator. Almost without exception, technology did not meet the goal of unencumbering the personnel operating the equipment

... systems often required exceptional human expertise, commitment, and endurance.

there is a natural synergy between tactics, technology, and human factors ... effective leaders will exploit every new advance to the limit. As a result, virtually every advance in ergonomics was exploited to ask personnel to do more, do it faster and do it in more complex ways.

... one very real lesson is that new tactics and technology simply result in altering the pattern of human stress to achieve a new intensity and tempo of operations. [edited to rephrase domain referents generically]

This statement could have come from studies of the impact of technological and organizational change in health care or air traffic management or many other areas undergoing change today (see Billings, 1997, and Sarter and Amalberti, 2000, for the case of cockpit automation). Overall, the studies show that when black box new technology (and accompanying organizational change) hits an ongoing field of practice the pattern of reverberation includes (Woods and Dekker, 2000):

- New capabilities, which increase demands and create new complexities such as increased coupling across parts of the system and higher tempo of operations,
- New complexities when technological possibilities are used clumsily,
- Adaptations by practitioners to exploit capabilities or workaround complexities because they are responsible to meet operational goals,
- The complexities and adaptations are surprising, unintended side effects of the design intent,
- Failures occasionally break through these adaptations because of the inherent demands or because the adaptations are incomplete, poor, or brittle,
- The adaptations by practitioners hide the complexities from designers and reviewers after-the-fact who judge failures to be due to human error.

The pattern illustrates a more general law of adaptive systems that has been noted by many researchers (e.g., Rasmussen, 1986; Hirschhorn, 1997)

The law of stretched systems:

every system is stretched to operate at its capacity; as soon as there is some improvement, for example in the form of new technology, it will be exploited to achieve a new intensity and tempo of activity.

Under pressure from performance and efficiency demands, advances are consumed to ask operational personnel to do more, do it faster or do it in more complex ways (see NASA's Mars Climate Orbiter Mishap Investigation Board report, 2000, for an example).

2. Watching People Engineer Cognitive Work: Claims and Myths

People as advocates for investment in and adoption of new technology make claims about how these changes will affect cognitive work and the processes and products of practice. Claims about the future of practice if objects-to-be-realized are deployed represent hypotheses about the dynamics of people, technology and work (Woods, 1998). Observations

at points of technology change find that these hypotheses can be and are often quite wrong a kind of second order automation surprise (Sarter, Woods, and Billings, 1997). Envisioning the future of operations, given the dynamic and adaptive nature of the process, is quite fragile.

What patterns emerge from observations of people engineering cognitive work or of people's claims about how various advances-in-process will enable the re-engineering of cognitive work? Remarkably consistently, we observe over-simplifications (Feltovich et al., 1997) that claim the introduction of new technology and systems into a field of practice substitutes one agent for another, essentially, computer capabilities as substitute for erratic human performance. Yes, the claims of opposition of human and machine come cloaked in different and often quite sophisticated forms, yet underneath inter-substitutability or Fitts' List remains the core people and machines are or can be equivalent so that new technology (with the right capabilities) can be introduced as a simple substitution of machines for people preserving the system though improving the results. This oversimplification fallacy is so persistent it is best understood as a cultural myth the Substitution Myth (Woods and Tinapple, 1999).

The myth creates difficulties because it is wrong, empirically adding or expanding the machine's role changes the cooperative architecture and changes human roles, introduces capabilities and complexities that are part of multiple adaptive cycles as human actors and stakeholders jostle in the pursuit of their goals. But moreover, the myth is unproductive as it locks us into cumbersome trial and error processes of development, blocks understanding the demands of cognitive work in context and how people in various roles and groups adapt to those demands, and channels energy away from processes of innovating use from the continually expanding power of machine information processing.

How can we better calibrate and ground claims about the future of cognitive work to avoid past cycles where change exacerbated clumsy use of technology and limited adaptations from people responsible to meet system goals? One possible tactic is to develop generalizations or laws that govern cognitive work by any cognitive agent or any set of cognitive agents from the empirical base. Such Laws could serve as a guide to enhance the use information processing technology in a practice-centered R&D process (Woods and Christoffersen, in press).

3. Predicting and Steering Change in Cognitive Work

Based on patterns about cognitive work and about the relationship of people and computers abstracted from research on cognitive work in context, I offer four families of Laws that Govern Cognitive Work as a synthesis to guide future development of human-computer cooperation (the approach is a deliberate play off Conant's 1976 laws of information that govern systems). I also offer Norbert's Contrast (Wiener, 1950) as an alternative conception of the relationship between people and computers. The current draft set of Laws is available from the author.

These laws are built on a foundation of agent-environment mutuality. Agents' activities are understandable only in relationship to the properties of the environment within which they function and an environment is understood in terms of what it demands and affords to potential actors in that world. Each is mutually adapted to the other.

The Laws fall into four families plus Norbert's Contrast. First, Laws of Adaptation build on original insights of cybernetics and control (Ashby, 1957; Conant, 1976). The driving force here is how cognitive systems adapt to the potential for surprise in the worlds of work, i.e., the foundational slogan for Cognitive Systems Engineering from Jens Rasmussen *adaptations directed at coping with complexity and surprise* (Rasmussen and Lind, 1981; Woods, 1988; Woods and Christoffersen, in press).

Laws of Models are concerned with how we understand and represent the processes we control and the agents we interact with. The driving force here is the mystery of how expertise is tuned to the future, while, paradoxically, the data available is about the past.

Laws of Collaboration address how cognitive work is distributed over multiple agents and artifacts. The driving force here is the fact that cognitive work always occurs in the context of multiple parties and interests as moments of private cognition punctuate flows of interaction and coordination. The idea that cognition is fundamentally social and interactive, not private, radically shifts the basis for analyzing and designing cognitive work and reconsidering the relationship between people and computers.

Quite surprisingly, Laws of Responsibility are the fourth family, driving home the point that in cognition at work, whatever the artifacts and however autonomous that are under some conditions, people create, operate, and modify these artifacts in human systems for human purposes.

Fifth, based on these Laws, Norbert's Contrast goes behind our fascination with increasing the power of the computer to remind us of the limits of literal minded agents and the unique competences of human cognition to handle the tradeoffs and dilemmas of a changing, finite resource, uncertain world (Wiener, 1950).

Norbert's Contrast

Artificial agents are literal minded and disconnected from the world, while human agents are context sensitive and have a stake in outcomes.

The key is people and computers *start* from different opposite points and tend to *fall back* or default to those points without the continued investment of effort and energy from outside the system.

Each of these families of Laws and Norbert's Contrast is quite surprising even shocking given conventional beliefs about cognition, organizations, and computers. The Laws allows us to see past these conventional beliefs to reconsider relationships across people, computers, the goals of various stakeholders and the complexities and variations in the worlds of human activity as we envision and create the future of operations.

Laws that Govern Cognitive Work have an odd quality—they appear optional. Designers of systems that perform

cognitive work do not have to follow them. In fact, we notice these laws through the consequences that have followed repeatedly when design breaks them in varying episodes of technology change. The statements are law-like in that they capture regularities of control and adaptation of cognitive work, and they determine the dynamic response, resilience, stability or instability of the distributed cognitive system in question. While developers may find following the laws optional, what is not optional is the consequences that accrue predictably from breaking these laws, consequences that block achieving the performance goals developers and practitioners, technologists and stakeholders set.

Respect for the Laws is essential, for in the final analysis: in design, we either hobble or support people's natural ability to express forms of expertise.

Acknowledgments

This piece is a companion and follow up to a previous address to the Cognitive Science Society in 1994, *Observations from Studying Cognitive Systems in Context*.

Many thanks to the various colleagues who in one way or another helped identify how generalizations like these operate in cognitive work.

Prepared in part through participation in the Advanced Decision Architectures Collaborative Technology Alliance sponsored by the Army Research Laboratory under Cooperative Agreement DAAD 19-01-2-0009.

Abstract

We explore current research on how complex visualizations are perceived, comprehended, used, and taught.

Introduction

How do people perceive, comprehend, and use complex visualizations, and when are they needed? Many domains (meteorology, scientific visualization, stock market analyses) deal with very complex data that must be displayed and used in novel ways. Unfortunately, very little is known about how these complex displays are used, how to best display complex graphical information, or how to design good complex visualizations for teaching purposes. This symposium will examine:

- how people understand and use complex visualizations;
- how people gain expertise in using complex visualizations;
- how to teach complex domains by using graphs and visualizations;
- how to visualize uncertainty across many variables;
- why a visualization is hard or easy to use; and
- how current models of graph comprehension scale up to more complexity.

Building Qualitative Mental Models

Greg Trafton

How do people use a complex visualization? Most current theories predict a straightforward process of reading off specific information, typically at the request of an experimenter. Many complex domains, however (many areas of scientific visualization, meteorology, etc.) need to deal with multi-dimensional data with complex interactions and anomalies.

I will present several recent studies that show that while experts mostly conform to the standard models of graph comprehension, there are some glaring holes in current theories. Specifically, experts do more than simply

read off information. First, they extract primarily qualitative information from complex visualizations (e.g., "The wind is fast over San Diego") even when quantitative information is available and needed later. With this qualitative information, they build a complex mental representation (which we call a qualitative mental model, or QMM) to reason with.

I will present data that shows how experts build these complex mental structures by looking at complex visualizations. I will also present evidence from eye-tracking and protocol studies of experts and novices working in their own domain, showing how novices seem to conform to the standard graph comprehension models while experts do not.

The Role of Prior Knowledge in Complex Data Comprehension

Priti Shah & Eric G. Freedman

People are increasingly faced with the task of interpreting complex*multivariate quantitative data sets. Unfortunately, much research on graph interpretation has focused on how novice (college undergraduate) viewers use common formats* (e.g., bar and line graphs) for simple tasks (e.g., read a data point or describe a trend) and sparse (2-3 variables and few data points) and meaningless (axes labeled x and y) data.* In our presentation, we argue that models based on this research may not scale up to account for more complex data interpretation, which differs in several key features. Complex data interpretation usually refers to tasks involving many variables, complex interactions between the variables, and a large number of data points. Complexity extends beyond simply data complexity, however. Dealing with complex data coincides with complex tasks (e.g., making decisions or explaining data) rather than fact retrieval.* Complex data also involves the extensive use of prior knowledge and viewers with data interpretation skills (experts use complex data, not novices).* Finally, complex data is often presented via

specialized displays that sometimes incorporate animation and interactivity. Models of complex data interpretation thus require considering data complexity, domain knowledge, graph reading skills, and display characteristics.

In a number of recent studies we consider how these factors play a role in viewers' interpretations. Our results suggest that domain knowledge and data interpretation skills influence viewers' comprehension and use of complex data. In addition, domain knowledge and data interpretation skills interact with data complexity and display characteristics. Specifically, prior knowledge reduces complexity in two ways: "experts know what to look for and also how to retrieve that information from complex displays." Second, prior knowledge reduces the influence display characteristics on viewers' comprehension of data. Third, prior knowledge helps viewers integrate data and theory and understand implications of the data. Finally, display characteristics such as interactivity and visual cues also reduce cognitive complexity.

We describe a model of graph comprehension based on these results. By incorporating the interaction of top down factors (e.g., domain knowledge) and the bottom up influence of display characteristics, our model builds on prior models but provides a more comprehensive description of complex data interpretation.

Visualizing Uncertain Information

Susan Kirschenbaum

There are many qualities that make visualizations complex. Perhaps the most clear-cut definition is the multi-variable visualization. The variables may be incompatible or difficult to display in a single visualization. For example, to display (in support of maneuver decisions) the course, speed, range, depth, time, and relative motion (how two moving objects relate to one another) of submarines moving through the sound field that is the ocean requires multiple complex visualizations. Weather forecasters have similar problems. The visualizations can be either graphs or, more often, geo-referenced displays.

Visualizations of these situations would be complex even without the added problem of uncertainty. However, the submarine world is characterized by the extensive uncertainty due to limited measurable data, indeterminate algorithmic solutions, and sound transmission characteristics underwater. Naturally, with multiple variables and uncertainties, there are many options for visualizing the problem. Some limit the number of variables; many ignore or discretize uncertainty. Alternatively, there are many ways to visualize uncertainty (Pang, et al., 1997). Even when uncertainty is not displayed, decision makers find ways to assess it by multiple comparisons; across variables of interest, and by comparing models with predicted, modeled, or measured data.

I will show evidence from verbal protocol and eye-tracking data of how decision makers interpret uncertainty in visualizations and of the impact of task and expertise on the effectiveness of various visualization options.

Designing representational systems to study complex visual cognition

Peter C-H. Cheng

Representational epistemology is the term I use to succinctly describe our work on the nature cognition with complex visualizations. The central theoretical claim of representational epistemology is that representational systems are fundamental to the highest forms of human cognition, such as problem solving, conceptual learning and scientific discovery. In such activities the acquisition and transformation of knowledge is essential, so understanding the nature of the representations that codify that knowledge will be critical. For instance, in the context of conceptual learning we theorize that an effective representation will substantially determine: what is learnt; how easily learning occurs; the nature of the conceptual structures that develop; the problem solving procedures that are acquired.

There are five common stages to our representational epistemological studies. First, a conceptually demanding knowledge rich domain is selected. Educational domains that we have addressed include mechanics, electricity and probability theory. The approach is also being applied to the intensive real-world problem of University examination scheduling. Second, the content and problem classes of the domain are analyzed to reveal the underlying conceptual structure of the knowledge, which includes the ontologies, perspectives, scale levels, laws, models, prototypes and extreme cases of the domain. Third, the existing domain representations are examined to uncover the conceptual problems they cause. Fourth, a new diagrammatic system is invented to encode the inherent conceptual structure of the domain. The novel representations that we have invented are Law Encoding Diagrams, LED. By directly reflecting the conceptual structure of a target domain in its representational structure a LED is a re-codification of knowledge that should support comprehension, problem solving and learning of the domain. The LEDs are of sufficient novelty and potential that papers describing them and their use have been accepted for publication in domain specific journals. Fifth, empirical evaluations of problem solving and learning with the new LED compared to the conventional representations of the domain are conducted in the laboratory or in Schools.

Studies conducted in the domains mentioned above show that LEDs improve problem solving and conceptual learning compared to the conventional domain representations. By generalizing over these different domains, contrasting the various LEDs and the existing representations, we are formulating principles for the design of effective representations for complex knowledge rich domains. Two classes are posited: semantic transparency principles that address how the underlying conceptual structure of a domain should be encoded in the inherent structure of the representation; syntactic plasticity principles that consider how a representation should be structured to support efficient problem solving.

Nature's Turing Test

Symposium Organized by:

Thomas R. Zentall (zentall@uky.edu)

Department of Psychology, Department of Psychology,
University of Kentucky, Lexington, KY 40506-0044

Introduction

What, if anything, is special about human cognition and how might we find out? This is the crux of the Turing test. In this symposium we suggest that identification of similarities and differences between humans and other species provides an opportunity to examine the Turing Test from a different perspective. Our goal is to show that the range of conceptual learning in nonhuman animals includes several of the of the major categories traditionally attributed to humans alone. Understanding concept learning in animals other than humans provides not only a more inclusive view of concept learning, but also provides a more objective perspective from which to understand the processes involved in such learning.

Perceptual Classes

Edward A. Wasserman, Department of Psychology,
The University of Iowa, Iowa City, IA 52242-1407

The most fundamental form of concept learning involves classification according to the perceptual attributes of objects (i.e., the features that they share). There is clear evidence that pigeons can sort complex stimuli into basic classes and that the basis for such sorting is similar to that used by humans (Bhatt, Wasserman, Reynolds, & Knauss, 1988).

Superordinate Classes

Thomas R. Zentall, Department of Psychology,
University of Kentucky, Lexington, KY 40506

At a more advanced level, animals have been shown to be capable of forming "superordinate" classes or functional equivalences. In a matching-to-sample task, pigeons that have learned to assign several arbitrary samples to a common comparison stimulus can be shown to develop emergent relations among those samples; later reassignment of one or more of those samples to a new comparison results in the untrained reassignment of the other members of the superordinate class (Urcuioli, Zentall, Jackson-Smith, & Steirn, 1989; Wasserman, DeVolder, & Coppage, 1992).

Relational Classes

Roger K. R. Thompson, Mary Jo Rattermann, and
Anthony P. Chemero, Whitely Psychology
Laboratories, Franklin & Marshall College,
Lancaster PA 17604-3003

We will present a series of results concerning the cognitive abilities of children, chimpanzees, and monkeys. By combining these results with research on pigeons (discussed by Wasserman and Zentall in this Symposium) and carefully designed simulations, we will demonstrate how comparative methods can be used to identify specialized, if not unique, human cognitive abilities. Specifically, we address the role of symbolic representation and the role of social factors in shaping the expression of abstract relational and analogical cognitive abilities.

The AMBR Model Comparison Project: Round III — Modeling Category Learning

Session Organizers: Kevin A. Gluck (kevin.gluck@williams.af.mil)

Air Force Research Laboratory
6030 S. Kent St., Mesa, AZ 85212 USA

Richard W. Pew (pew@bbn.com)

BBN Technologies
10 Moulton St., Cambridge, MA 02138 USA

The goal of the Agent-based Modeling and Behavior Representation (AMBR) Model Comparison Project is to advance the state of the art in cognitive modeling. It is organized as a series of model comparisons, moderated by a team from BBN Technologies. In each comparison, a challenging behavioral phenomenon is chosen for study. Data are collected from humans performing the task. Cognitive models representing different modeling architectures are created, run on the task, and then compared to the collected data. The current effort focuses on models of category learning in a dynamic, dual-task environment. Model comparisons such as this, especially with directly comparable human data are rare. While models of category learning are commonplace, the fact that these are models of integrative performance, not just models of category learning in isolation, makes this set of presentations unique.

Experiment Design and Comparison of Human and Model Data

David Diller (ddiller@bbn.com)
Yvette Tenney (ytenney@bbn.com)
BBN Technologies

This experiment involved a classic concept learning task embedded in an air traffic control situation. Subjects had to learn to make correct decisions to accept or reject altitude change requests, based on three bi-variate properties of the aircraft (percent fuel remaining, aircraft size, and turbulence level). A novel feature of the experiment was the addition of multi-tasking to this concept learning paradigm. In addition to the altitude change requests (the concept learning task), the participant had to hand-off a number of aircraft to adjoining controllers (secondary task).

The design consisted of 9 conditions, defined by 3 category structures and 3 workload levels. The three category structures, borrowed from Shepard, Hovland, and Jenkins (1961), were: single attribute relevant (Type I), a single-attribute rule plus exceptions (Type III), and no rule (Type VI). The three workload levels consisted of 0, 12, or 16 required handoffs, in addition to the 16 altitude requests. It was expected that both category structure and workload level would affect performance. There were 8 scenarios, or trials, lasting ten minutes each. One hour of training on the mechanics of the tasks preceded the trials.

Ninety humans and four different human performance models described in subsequent abstracts were run through the scenarios. The interface, consisting of a radar screen

with moving aircraft and action buttons, was designed to accommodate both humans and models. Humans were randomly assigned to one condition (ten per condition). The models were run one or more times in each condition.

All of the modelers were given the human learning data as soon as they were collected, and while the models were still under development. It was expected, therefore, that they would fit the data fairly well. However, a transfer test (for which the modelers were not given the human data in advance) provides an opportunity to test the generalizability of the models predictions.

Results for both humans and models will be presented on the effects of category structure and workload over trials. Human data and model data are available for the following measures: learning curves (probability of error) on the concept learning task, performance errors on the secondary task (missed and incorrect actions), reaction time on both the concept learning and secondary task, self rated workload ratings (collected from models too!), and self-reports on rule discovery and other strategies on the concept task (humans only). This presentation will set the stage for the modelers to describe the mechanisms and assumptions that allow their models to replicate the results.

An EPIC-Soar Model of Concurrent Performance on a Category Learning and a Simplified ATC Task

Ron S. Chong (rchong@gmu.edu)
George Mason University
Robert E. Wray (wrays@soartech.com)
Soar Technology, Inc.

During the first phase of the AMBR project, we developed a model of a simplified en-route air traffic control task. That model was built using the EPIC-Soar architecture, an integration of the perceptual and motor systems of the EPIC architecture with Soar, a learning cognitive architecture. The task to be modeled for the current phase of AMBR is the combination of the same ATC task with a new concept acquisition task. Our approach to building the new model has been to reuse, in a modular fashion, previous Soar models for the subtasks. The ATC model is essentially the same as that of the previous AMBR phases. To produce the learning behavior, we have incorporated an existing process model of concept learning called SCA (symbolic concept acquisition). SCA was developed in Soar and has been

successfully used in many Soar applications and models that require concept learning. Results of the model will be presented.

Developing Concept Learning Capabilities in the COGNET/iGEN Integrative Architecture and Associated AMBR ATC Model

Wayne Zachary (wayne_zachary@chiinc.com)
CHI Systems, Inc.

A concept learning mechanism has been added to the COGNET/iGEN modeling and human performance simulation system, and the model developed in Rounds 1 and 2 of the AMBR model competition has been extended to add the learning task. The learning mechanism developed enables learning of the conditions under which a task or goal should or should not be pursued, in addition to the current mechanism of evaluating a predefined boolean expression against contents of declarative memory. Building on the premise that concept learning can be characterized as hypothesis testing, the learning mechanism incorporates a metacognitive strategy for hypothesis generation and an hypothesis selection process based on memory for previous exemplars and their feedback, as well as previous rules or rule parameters tried, moderated by attentional and forgetting processes. The integration of the learning mechanism into the COGNET/iGEN architecture and the extended ATC model results will be presented.

An Activation-based Theory of Categorization

Christian Lebiere (cl+@cmu.edu)
Carnegie Mellon University

We propose a model of category learning implemented in the ACT-R cognitive architecture (Anderson & Lebiere, 1998). ACT-R is a hybrid architecture that combines a symbolic production system with a subsymbolic activation calculus. Our model is directly grounded in the constraints provided by the architecture, especially its declarative memory retrieval mechanism. Generalization to new instances is produced by a similarity-based partial matching mechanism that operates at the subsymbolic level. A number of latency predictions that had previously been explained in terms of a random walk process arise from an aggregate retrieval mechanism called blending. These subsymbolic mechanisms provide many of the advantages of connectionist systems while preserving inspectability at the symbolic level. The category learning model was added in a modular fashion to the existing ATC model from previous AMBR rounds.

Concept Learning: Knowing and Reasoning in the DCOG Architecture

Robert G. Eggleston (robert.eggleston@wpafb.af.mil)
Air Force Research Laboratory
Katherine L. McCreight (kate@n-spaceanalysis.com)
N-Space Analysis

DCOG is an emerging architecture of cognition. It treats cognitive behavior in terms of organized state changes that occur across a set of subsystems. Concept learning may be achieved in the architecture either by emergent knowing, derived from low-level feature-based recognition, or by higher-level reasoning using more abstract feature-derived knowledge that supports hypothesis formation and testing. In this study, a DCOG model was used to perform a complex air traffic control task that contained a concept-learning component. The concept-learning subtask was patterned after the classic Shepard, Hovland, and Jenkins (1961) task but limited to types 1, 3, and 6. Given the structure of these concept types and the balanced exemplar presentation history used in the experiment, both the knowing and reasoning pathways are viable for type 1 concepts; but only the reasoning path is viable for types 3 and 6. Both the knowing and reasoning pathways support individualistic variations or strategies and thus can emulate individual subject differences. In this presentation, we describe the feature-based concept learning infrastructure of DCOG and discuss its performance on the ATC task.

Symposium Discussant

Bradley C. Love (love@psy.utexas.edu)
University of Texas

Human category learning takes many forms, yet research in category learning has focused almost exclusively on one narrowly defined task: classification learning with no secondary task. This focus has allowed researchers to understand and explore their predictions in detail, but only within a circumscribed domain. Unfortunately, theoretical progress (as well as practical application) also demands the testing of boundary conditions. In many cases, we simply do not know how well our theories of learning generalize across task situations and induction tasks. The work presented in this symposium is an important step towards developing more general theories of learning that can make contact with human performance outside the laboratory.

Acknowledgments

AMBR Round III is sponsored by the Air Force Research Laboratory and the Office of Naval Research.

Overview

Inquiry is one of the oldest areas of research in cognitive science, and one of the most interdisciplinary, drawing upon social and cognitive psychology, computer science, philosophy, and educational research. It also demonstrates how cognitive science can flourish at the intersection of theory and practice, with findings from one informing, constraining, and validating the other. There are obstacles to fully realizing this integration, however. Differences in population, setting, methodology, and epistemology have resulted in a patchwork of ideas that we have not quilted together into a functional unit.

Looking at this landscape, several questions emerge that reflect the piecemeal nature of this research. We tend to be ambiguous about what it means to conduct an inquiry, and about why a good inquiry is a good inquiry, defining it primarily in terms of the particular task at hand. We do not really know which features of inquiry are specific to a certain environment, goal, or population, and which features are domain-general. Perhaps of particular importance to those of us with educational interests, we are not always in agreement regarding what effect research in inquiry has in establishing standards, curricula, testing, and assessment, influencing what it means to be "rational," "clear-thinking," and "educated."

Our goal is to get at these questions and issues by bringing together multiple threads of research and making a concerted effort to outline areas of consensus and dissent. Limiting ourselves to the subarea of computer-assisted inquiry about scientific matters, each of us will summarize within and across our own programs of research. Together, we cover a variety of methodologies and settings, from experimental psychology in laboratories, to design experiments in classrooms, to ethnography in online communities. We will attempt to synthesize answers to a set of questions inspired by the interplay of theory and practice:

1. **The Nature of Inquiry.** What is inquiry? What does effective inquiry look like, what does it require, and what does it produce?
2. **Technology, Inquiry & Situated Cognition.** How is the form and function of inquiry facilitated and/or impeded by the environment? Which processes are generalizable? Which are embedded in the particulars?
3. **Educational Implications.** What are the implications of theory for educational practice, and vice versa?

Symposium: New Models of Connectionist Language Acquisition

Ping Li (pli@richmond.edu)

Department of Psychology, University of Richmond
Richmond, VA 23173 USA

Brian MacWhinney (macw@cmu.edu)

Department of Psychology, Carnegie Mellon University
Pittsburgh, PA 15213 USA

Connectionist modeling of language acquisition has attracted strong research interests in the past decades since Rumelhart & McClelland's (1986) pioneering model of the acquisition of the English past tense. Significant progresses have been made in this domain, as reflected in Elman et al. (1996), MacWhinney (1999), and more recently in Quinlan (2002). In this symposium, we propose to integrate current connectionist developmental research related to language. We present to CogSci 2002 a variety of new models in connectionist language acquisition, including an SRN model of generalization (Elman), a self-organizing model of categorical representation (Li, Farkas, & MacWhinney), and an encoder network of concept acquisition (Shultz).

In the first talk entitled "Going beyond the input: the problem of generalization from sparse data", Elman will discuss the issue of how children form generalizations given the inputs available to them. Although in quantitative terms children hear an enormous amount, that input provides only a very sparse representation of the language. Given the presence of numerous gaps in the input, how is a child to know when a gap is accidental and when a gap is systematic? Several connectionist simulations suggest the kinds of constraints on induction that may explain the patterns of both under- and over-generalization that are observed in children.

In the second talk entitled "The origin of categorical representation of language in the brain", Li, Farkas, and MacWhinney will start by considering the "brain centers" of language, areas in the brain that respond to different linguistic categories (e.g., nouns and verbs). A working hypothesis underlying "brain centers" is that different linguistic categories are subserved by different neural substrates. This study examines the emergence of categorical representation from a developmental connectionist perspective. It argues that localized linguistic representations arise as a function of the brain's organization and reorganization in response to characteristics of the environment in learning and development. A self-organizing neural network is used to explore the high-dimensional space of various linguistic categories, analyzing realistic natural language data. The model effectively captures such differences in language use.

In the third talk entitled "Acquisition of crisp and fuzzy concepts", Shultz will discuss concept acquisition by neural networks. Crisp concepts possess such rigid boundaries that instances of one concept are rarely confused with another

concept. In contrast, fuzzy concepts have vague boundaries, leading to frequent misclassifications. The feature values of fuzzy concepts are considered probabilistic in that they occur in instances with less than certain probabilities. This generates well-known typicality and prototype effects, with some instances considered better exemplars of a fuzzy concept than others are. Although neural network models provide an adequate account of fuzzy concepts, they are, according to some, incapable of accounting for the acquisition and representation of crisp concepts as in, e.g., kinship terms. Simulations with encoder networks show that this view is fundamentally incorrect: encoder networks can account for a wide range of phenomena associated with concepts along the crisp-fuzzy continuum. Representational crispness in these networks is affected by isolation of the concept in semantic feature space and dispersion of its examples around a prototype. Fuzzier concepts are characterized by residence in a relatively crowded region of feature space and by relatively widely dispersed examples; crisper concepts are characterized by residence in a relatively isolated region of feature space and by relatively limited dispersion of examples. Moreover, the presence of defining features immunizes these networks against the normal *fuzzifying* effects of conceptual crowding and example dispersion. Simulations also revealed the familiar developmental shift from characteristic to defining features.

Li will give an overview at the beginning of the symposium, and MacWhinney will provide an integrative discussion at the end. Each talk is scheduled for 25 minutes, including discussion and questions from the audience.

Publication-based Talks

Coordination of Talk & Action

Richard Alterman (alterman@cs.brandeis.edu), Alex Feinman, Seth Landsman, Josh Introne

Computer Science Department, Center for Complex Systems, Brandeis University
415 South Street, Waltham, 02454 USA

The participants in a joint activity must work hard to maintain coordination. For complicated and/or novel activities, even more talk is needed to proceed. Over time, for recurrent cooperative behaviors, the participants will organize their talk as a means of organizing their actions. For recurrent activities, a sign may be introduced at the scene to fix a recurrent problem of coordination by providing some organizational structure (e.g., a stoplight). We will refer to permanent structure designed and implemented prior to a cooperative activity by a non-participant that mediates and organizes the activity as a *coordinating representation*. The main work of this talk is to explore the ramifications of, and methodology for, introducing coordinating representations into same-time / different-place computer-mediated cooperative activities.

Groupware systems are computer-based systems that support groups of people engaged in a common task (or goal) and that provide an interface to shared environments (Ellis et al, 1991). Groupware facilitates communication, coordination, and collaboration of group effort. Building a groupware system requires a detailed analysis of the work environment in which it will be deployed and extensive work on designing both the interface as it presents itself to the individual user and the mediated interaction among the users.

Within the literature on CSCW, the development of technology that supports online communication has been a core research issue. For synchronous communication, the canonical example is to convert an everyday task of several actors engaged in planning out some kind of activity in front of a whiteboard into a task that could be computer-mediated. Given the shared workspace, two issues of interest are how the participants in such an activity organize their talk, and how they organize their task.

Where a shared virtual whiteboard is an external media that can be used to support all kinds of social interaction, a coordinating representation is one kind of content realized in an external media. It is specifically designed for a particular context and it addresses a problem of coordination that emerges in the performance of a recurring cooperative activity across sessions of cooperation. For some applications, general-purpose tools that support communication and coordination, like the whiteboard, will suffice. But for tasks that occur over extended periods of time, the introduction of a coordinating representation will potentially improve the interaction among the participants during the recurrent problematic areas of joint behavior. This scheme leverages the user's participation to help make the system tailor-made.

Figure 1 shows the basic methodology we propose for tailor-making a groupware system. A groupware system is developed providing general-purpose coordination tools to support the users' activity. In some cases there are difficult problems in coordination that confront the users during the normal course of their mediated behaviors and these problem areas are not easily or efficiently resolved using general tools. In these cases a pilot study is performed, and a discourse analysis is made to identify secondary structure developed by the participants to organize their talk so as to organize behavior. Based on this analysis, a second version of the system is constructed that includes coordinating representations to support user activity.

In the first part of the talk I will lay out the cognitive foundation for this approach to building tailor-made groupware systems. In the second part of the talk, I will present a methodology, focusing on issues and methods of discourse analysis. Data and evidence for this talk are drawn from both prior and existing work (and studies) at Brandeis. The examples we draw on come from the data we have collected from experiments we have performed using the VesselWorld system, demonstrated at CSCW 2000.

1. Build a base system that includes general-purpose coordination tools only (e.g., whiteboard, textual chat)
Sometimes this is enough
2. Perform pilot study with base system
3. Analyze data to discover recurrent problems of coordination and what secondary structures are devised to organize those behaviors.
4. Rebuild system using coordinating representations suggested by analysis.

Developing and Validating Cockpit Interventions based on Cognitive Modeling

Deborah A. Boehm-Davis (dbdavis@gmu.edu)

Robert W. Holt (bholt@gmu.edu)

Melanie Diez (mdiez@gmu.edu)

Jeffrey T. Hansberger (jhansber@gmu.edu)

Department of Psychology, George Mason University
4400 University Dr., Fairfax, VA 22030 USA

Aviation accidents are a rare event. However, when they do occur, the cause is attributed to "human error" over 60% of the time (National Transportation Safety Board, 1994). This suggests that the greatest increments in safety can be gained by improving human performance. Indeed, the typical response to an accident investigation is changes to operating procedures that pilots follow in the cockpit. However, in these situations, the changes are made in response to one specific event, which does not allow researchers to pinpoint the more general causes of errors. Further, this approach is not suited to understanding the process of pilot-system interaction that results in the errors. This makes it impossible to know how to design interventions such as training (Boehm-Davis, Holt, Hansberger, & Seamster, 1999), how to redesign instruments, displays, or software, or how to assess the effects of the intervention.

In this research project, we took an alternative approach by developing a computational model of the cognitive processes underlying pilot performance while flying a descent in an automated cockpit. The computational model was built from a cognitive task analysis coupled with empirical performance data. The cognitive task analysis of these phases was developed using NGOMSL (Natural Language GOMS, see Kieras, 1997). This information was combined with eye tracking data taken from pilots interacting with a low-fidelity desktop simulator of a 747-400 aircraft cockpit (Diez et al., 2001) to inform our design decisions about what information pilots are acquiring from the flight deck while working with automated systems. It also formed the basis of a working computational cognitive model, built using the ACT-R cognitive architecture (Anderson & Lebiere, 1998).

The computational model was used to fly the same descent that our pilots had flown on the desktop simulator. Observations of the problems encountered by the model in flying the simulator suggested a number of interventions that might mitigate error in the cockpit. Two of these interventions were selected for empirical testing. First, model runs and eye track data both suggested that the pilots/model were often unaware of changes in automation mode that were driven by the software rather than the pilot (i.e., uncommanded mode changes). A potential intervention developed for this problem is a chime that rings in the cockpit to indicate that the flight management system has autonomously changed the flight mode. We believe that this

intervention will draw attention to mode changes that can then be diagnosed and understood.

Second, when the model was interrupted, it often was unable to remember the goal that it was trying to achieve; thus, the model was unable to continue flying. For this problem, new annunciations have been developed for display in the cockpit to capture the goal the automated flight system is trying to achieve. We believe that this goal-oriented display will provide guidance to the pilot about what the flight management system is doing, which can help pilots reconstruct their interrupted goal.

Empirical data collected from commercial pilots using the modified flight management system on the desktop simulator suggests that these interventions will be useful in reducing these specific errors in the cockpit. Further work remains to determine the more general benefits of these interventions.

The Information-Processing Function of Conscious Intentions

Richard A. Carlson (racarlson@psu.edu), Lisa M. Stevenson (lms152@psu.edu), Marios N. Avraamides (marios@psu.edu), and Daniel N. Cassenti (dnc112@psu.edu)
Department of Psychology, Penn State University
613 Moore Building, University Park, PA 16802 USA

We argue that conscious intentions are central to the cognitive control of activity, in contrast to the view that the experience of conscious control is an illusion (Wegner & Wheatley, 1999). We suggest that instantiating a goal to form a conscious intention serves the information-processing function of establishing a procedural frame of reference that organizes mental activity. Information that specifies the origin of this frame of reference simultaneously specifies the conscious agent, the "I" who performs the action. This *cospecification hypothesis* is part of a more general theory of consciousness (Carlson, 1997). We briefly describe this hypothesis and its theoretical basis, and consider several empirical predictions and results bearing on those predictions.

Theory and Hypotheses

The cospecification hypothesis suggests that the content of a conscious intention represents the self as achieving an outcome by performing an operation on an object. For example, a conscious intention to add two digits represents the self as performing a calculation on particular tokens of those digits. Activating this representation serves to initiate a procedure to which the digit tokens are assimilated, and to establish a subjective "point of view" from which the digits are considered. The representation of an outcome that satisfies a conscious intention will thus be structurally very similar to the representation of the intention. This description parallels the representation of goals in ACT-R (Anderson & Lebiere, 1998), in which operands and results complete slots in the goal representation.

Our research has considered several implications of this hypothesis for the information-processing dynamics of goal-driven cognition. First, goal instantiation must precede effective consideration of objects to be processed (operands). Second, the availability of information specifying goals should constrain the temporal coordination of processes such as managing working memory and picking up information from the environment. Third, failures of coordination (e.g., placekeeping errors) should be reduced by activities or information that increase the spatial and temporal precision with which the acting self is specified. Fourth, the need to update the self's spatial and temporal location and orientation should constrain the strategies available for organizing sequential activities; for example, activating an intention directed toward appropriate objects may depend on updating one's perspective on the prior step. Fifth, the construction of explicitly retrievable episodic memories should be associated with goal instantiation

because it involves "taking note" of the self as a spatial and temporal marker.

Empirical Results

We have examined each of these implications, using experimental paradigms that examine skilled performance of mental sequences in which the environmental availability of information is constrained. For example, in a number of studies participants solved cascaded, multiple-step arithmetic or spatial path problems in which the outcome of each step served as a starting point for the next step. These studies provide support for the first and second predictions outlined above. Under temporal constraints, individuals can effectively coordinate information pickup and cognitive processes – a process we call *temporal tuning* – only when information specifying upcoming goals is available, allowing those goals to be instantiated as intentions.

In another series of studies, we examined the use of externalizing strategies such as pointing that serve to support temporal coordination. In these experiments, participants performed simple tasks such as counting under varying temporal and strategy constraints. The results suggest that externalizing strategies can serve both to enhance the individuation of objects to be processed (coordination between steps) and to reduce intention-outcome confusions (coordination within steps).

We consider these and other results in relation to the hypotheses sketched above.

Conclusions

In general, these studies provide support for the predictions derived from the cospecification hypothesis. However, some predictions have been disconfirmed in ways that suggest further hypotheses about the constraints on explicit goal instantiation. For example, neither procedural nor explicit declarative knowledge of operator sequences allows the temporal tuning observed when operators are specified by displayed information. We consider the implications of these successes and failures for the general theory of consciousness described in Carlson (1997).

Activity awareness in computer-supported collaborations

John M. Carroll (carroll@cs.vt.edu)

Center for Human-Computer Interaction and Department of Computer Science, Virginia Tech
660 McBryde Hall, Blacksburg, VA 24061-0106 USA

In order to collaborate effectively one needs to know many things about one's collaborators: Who are they? What do they know? What do they expect? What do they want to do? What are they doing now? What tools are they using? To what other resources do they have access? What are they thinking about? What are they planning to do in the near future? What criteria will they use to evaluate joint outcomes?

In ordinary face-to-face communication, people work to establish and maintain a shared background of understanding called common ground (Clark, 1996). Conversational interaction involves continual testing for evidence of common ground, and coordinated effort to enhance common ground. For example, if an interlocutor fails to respond to a request, one might restate presupposed information, point to a relevant object, request acknowledgement, or otherwise remediate. Common ground is unproblematic in face-to-face interactions because such a wide variety of situational elements contribute to it, and the work that people do to maintain common ground is so well integrated into habits and conventions of interaction.

When people work collaboratively, but not face-to-face, many interaction resources are disrupted (Tang, 1991): field of view is reduced, the possibility to use gesture is limited, facial expressions are eliminated or constrained, auditory cues are diminished, tools and artifacts cannot be as easily shared, exchanged information is delayed or decoupled by seconds or even minutes, and collaborators may be in different time zones or different cultures. In remote collaboration it is difficult to convey or discern successful comprehension, current focus of attention, or concomitant attitudes and affect. It is difficult to repair or remediate miscommunications. This transforms the maintenance of common ground into a significant task, which is itself problematic: People are accustomed to taking common ground for granted, as a background task. They do not want to spend attention and effort on it.

These issues have made awareness an increasingly prominent issue in the design of user interfaces for computer-supported collaboration. Investigators have explored numerous user interface tools to help collaborators establish and maintain common ground by supporting their mutual awareness of one another. Prior research has focused on *social awareness* (of the presence of one's collaborators) and *action awareness* (of what collaborators are doing or what they have recently done). Tools investigated include video tunnels (for social awareness) and radar views (for action awareness).

To effectively coordinate complex projects, collaborators need to be aware of one another beyond mere presence and

individual actions. We are developing the concept of *activity awareness* (Carroll et al., 2002). Activities are longer term endeavors directed at meaningful goals like "designing the layout of a town park". Longer term activity entails top-down goal decomposition, nonlinear development of partially-ordered plan fragments, interleaving of planning, acting, and evaluation, and opportunistic plan revision. It involves coordinating and carrying out different types of task components, such as assigning roles, making decisions, negotiating, prioritizing, and so forth. These components must be understood and pursued in the context of the overall purpose of a shared activity, the goals and requirements for completing it, and how individual tasks fit into the group's overall plan.

Contemporary user interfaces support collaborative awareness through explicit notifications—requests for chat, email alerts. However, explicit messaging is problematic for supporting activity awareness: Activities are multifaceted and continuing, not simple and ephemeral like presence and action. Thus, notification messages for activity awareness must be meticulous and persistent. But creating such notifications is itself a significant task. It compels a discipline of explicitly externalizing and broadcasting one's goals and plans, something people perceive as both tedious and invasive (Grudin, 1994).

Our work is pursuing the strategy of supporting activity awareness by designing workspace views that embed activity awareness documents. One example is a timeline view of a shared file system that incorporates deadline, active task, and version documents. In such an environment, collaborators would directly, but incidentally, understand the status of a shared activity as they participate in it.

Testing the Roles of Design History and Affordances in the HIPE Theory of Function

Sergio E. Chaigneau (schaig@uta.cl)

Departamento de Psicología, Universidad de Tarapaca
Av. General Velasquez 1775, Arica, CHILE

Lawrence W. Barsalou (barsalou@emory.edu)

Department of Psychology
Emory University, Atlanta, GA 30329

Two views currently dominate theories of object function. According to the affordances view, function arises from an object's structure and use; the object's design history is relatively unimportant. According to the historical view, function reflects the intention of an object's creator; structure and use are relatively unimportant. A new view, the HIPE theory, integrates the affordance and historical views, proposing that function cumulatively requires history, goals, structure, and use to be complete (Barsalou, Sloman, & Chaigneau, in press; also see Chaigneau & Barsalou, in press; Chaigneau, Barsalou, & Zamani, 2002).

Three experiments in Chaigneau (2002) tested the HIPE theory. In each, participants read scenarios that described an artifact's design history and physical structure, along with an agent's goal and actual use. After reading a scenario, participants either rated how appropriate a name was for the object ("mop"), how well the scenario illustrated a category's function (mop), or how likely the scenario was to cause the functional outcome (sopping up spilled liquid). In the baseline scenarios, all four components were intact. In the critical scenarios, one or more components were compromised. Design history could be accidental instead of intentional; the goal to use the object for its function could be absent; the physical structure could be insufficient; the action could be insufficient.

As predicted, Experiment 1 found that compromising each component reduced an object's functionality relative to baseline, consistent with HIPE's prediction that all four components are cumulatively necessary for a complete function. However, compromising structure and use generally produced the largest decrements, consistent with the affordances view. Furthermore, design history was more important for naming than for function and causality judgments, consistent with the causal link between history and naming in historical theories.

Experiment 2 tested the historical view's assumption that design history is causally sufficient for function. If so, then compromising any other component after compromising history should have no effect. Compromising goals, however, produced an additional decrement, consistent with HIPE's cumulative view.

Experiment 3 explored the finding in recent experiments that history is more important than structure and use in naming (e.g., Gelman & Bloom, 2000; Matan

& Carey, 2001). In these studies, however, the scenarios lacked sufficient detail about structure and use to derive affordances, thereby leaving history as the most informative factor. When sufficient information was provided so that participants could derive affordances, history became much less important for naming than structure and use.

Overall, these three experiments support three conclusions. First, function is a cumulative construct. Second, affordances are more central to this construct than history, although both are cumulatively important. Third, history is particularly important for naming, and less so for understanding function conceptually and reasoning about it causally.

Misrepresenting Emergent Causal Processes as Non-Emergent: A Potential Schema for Overcoming Misunderstandings in Science

Micheline T. H. Chi (chi@pitt.edu)

Learning Research and Development Center, University of Pittsburgh
3939 O'Hara Street, Pittsburgh, PA 15260 USA

Middle and high school students encounter numerous scientific and "everyday" processes in their curriculum. Some of these processes (e.g., electricity, heat flow, natural selection) seem particularly troublesome for them to learn with deep understanding. One reason for this difficulty is that students often possess alternative conceptions (or misconceptions) that are naïve and scientifically incorrect. These misconceptions are extremely robust and resistant to instruction, therefore preventing students from acquiring the correct understanding.

This paper provides a conceptual analysis that explains why there is a barrier in understanding these processes and what can be done to overcome it. The analysis essentially suggests that these often-misunderstood concepts are bi-level processes in which the global level pattern emerges from the collective individual actions/interactions at the micro level. Thus, the explanatory mechanism that causally relates the micro and the macro levels is an emergent one. Students, however, intuitively misrepresent an *emergent* mechanism as a kind of a non-emergent (or *direct*, for lack of a better term) causal mechanism.

Two types of features of the underlying explanatory mechanisms of *emergent* causal and *direct* causal processes are identified. One type of feature, shown in Table 1, describes the nature of the behavior of the individuals at the micro level. The behavior (i.e., the actions/interactions) of the individuals of an emergent causal process suggest that their actions/interactions must be considered as a *collection*, whereas the behavior of the individuals of a direct causal process suggest that their actions/interactions can be partitioned into distinct *classes*. Thus, this set of six features can serve the purpose of helping students recognize when it is appropriate to consider a set of actions/interactions collectively rather than distinctively.

Table 1: Six features of the actions/interactions (A/I) of individuals in a collection versus classes.

Emergent (Collection)	Non-Emergent (Classes)
<ul style="list-style-type: none"> • Same kind of A/I • Random A/I • Co-occur or parallel • Independent A/I • Uniform status • Ongoing, continuous 	<ul style="list-style-type: none"> • Different kind of A/I • Fixed A/I • Sequential or linear • Dependent A/I • Unique or central status • Bounded, terminating

The second set of five features, shown in Table 2, describes the relationship between the micro and the macro levels. These bi-level relational features are the ones that students can appeal to in explaining the causal relationship between the levels. These two sets of features, together, provide a preliminary specification of *emergent* causal and *direct* causal schemas. The claim is that students use their *direct* causal schema to interpret processes with an emergent explanatory mechanism, and therefore misunderstand them.

Table 2: Five features relating the micro individual and macro aggregate level.

Emergent	Non-Emergent
<ul style="list-style-type: none"> • Indirect • All individuals • Local & decentralized • Disjoint • Collective summing within each instance of time 	<ul style="list-style-type: none"> • Direct • Some of the individuals • Goal-directed & intentional • Corresponding • Cumulative summing across time

Several reasons can be postulated for why students commit such misattributions. First, these 11 features, being mutually exclusive, suggest that *emergent* causal and *direct* causal processes may be ontologically distinct; therefore, repairing such misconceptions requires a radical conceptual shift. Second, students may not even realize that they have misrepresented an emergent kind of causal process as a direct kind. Without such awareness, they lack the motivation to seek ways of re-representing emergent processes correctly. Third, students may altogether lack an emergent schema. Without such a schema, students cannot correctly conceptualize an emergent process. Finally, people in general might have a natural predisposition to interpret all events as a direct causal kind.

The implication of this analysis is that teaching students an emergent schema of the underlying explanatory mechanism may allow them to discriminate an emergent kind of causal process from a non-emergent kind, which then may lead to improvements in their understanding of emergent concepts across various disciplines.

Protocol Evidence On Thought Experiments Used By Experts

John J. Clement (clement@srri.umass.edu)

Scientific Reasoning Research Institute
College of Natural Sciences and Mathematics
and School of Education
Lederle GRT 434
University of Massachusetts
Amherst, MA 01003 USA

Despite recent advances, the Fundamental Paradox of Thought Experiments continues to challenge us: How can findings that carry conviction result from a new experiment conducted entirely within the head? The data base for this study comes from ten professors and advanced graduate students in scientific fields who were recorded while thinking aloud about the following spring problem:

A weight is hung on a spring. The original spring is replaced with a spring made of the same kind of wire, with the same number of coils, but with coils that are twice as wide in diameter. Will the spring stretch from its natural length more, less, or the same amount under the same weight? (Assume the mass of the spring is negligible.) Why do you think so?

Clement (1989) documented analogies, Aha! insights and cyclical model evaluation and revision processes in these protocols. Working from these transcripts, a variety of untested thought experiments (in the *broad sense*) have also been identified, characterized as the act of making a prediction for an untested, concrete, but absent situation (the *experiment*). Aspects of the experiment must be new and untested in the sense that the subject is not informed about its behavior. In a case study of one subject, S2, whether the spring wire is bending or twisting eventually becomes a central issue. Textbooks tell us that it is twisting, whereas many subjects assume bending. S2 examined what the effect of twisting would be in the following *Elemental untested thought experiment* used to make a prediction for the base of an analogy to short and long rods being twisted:

(1) If I have a longer (raises hands apart over table) rod and I put a twist on it (**moves right hand as if twisting something**), it seems to me--again, physical intuition--that it will twist more...I think I trust that intuition. I'm **imagining holding something** that has a certain twistiness to it, **a-and twisting it**. Now I'm confirming (**moves right hand close to left hand,)** that.. As (repeats motion) I bring my hand up closer and closer to the original place where I hold it, I realize very clearly that it will get harder and harder to twist.

Bold type above identifies examples of (both kinesthetic and other) imagery-related observation categories: personal action projections, depictive hand motions, and dynamic imagery reports, in that order. None are infallible indicators on their own, but together they are most plausibly explained using a framework that includes flexible perceptual motor schemas that generate and run imagistic simulations, via the

extended application of a schema outside of its normal domain, implicit knowledge, or spatial reasoning (Clement, 1994). One can point to such sources as potential origins of conviction in TEs, to help us begin to explain the fundamental paradox. They can also explain the effectiveness of the extreme case at the end of the transcript above as an example of imagery enhancement, a phenomenon difficult to explain in other ways (*ibid.*).

A second concept of TE in a *narrower sense* that I have found useful is what I call an evaluative Gedanken experiment: This is a special kind of untested TE designed or selected by the subject to help evaluate a concept, model or theory. An example is the case of a spring made of a vertically oriented band of material (the reader might imagine the metal unwound from a coffee can, reshaped to make a spring, say, 3 wide.) The subject imagined that such a spring would still be quite stretchable even though it cannot bend in the up-down direction, challenging the necessity of bending as not particularly relevant at all. In this type of evaluatory Gedanken experiment he designs a special case where the bending model yields a prediction, (no stretch) but where he also has some other independent source of information that can evaluate that prediction.

I believe both the broad and narrow concepts of TEs as clarified here are useful, and both can be analyzed in think aloud protocols. The broad concept is appropriate for expressing the fundamental paradox. The narrower concept of an evaluatory Gedanken experiment encompasses some famous TEs in the history of science, impressive in that they can even contribute to eliminating an established theory.

Putting Geometry and Function Together—Towards a Psychologically-Plausible Computational Model for Spatial Language Comprehension

Kenny R. Coventry¹ (kcoventry@plymouth.ac.uk), Angelo Cangelosi² (angelo@soc.plymouth.ac.uk),
Dan Joyce² (danj@soc.plymouth.ac.uk) and Lynn V. Richards¹ (lynnr@soc.plym.ac.uk)

Describing the position of objects in space necessitates a mapping between the spatial representation(s), computed by the visual system, and the language processing system. However, it turns out that spatial description is influenced not only by *where* objects are in space, but also by the *functions* that objects afford, and the functional relations between objects. For example, the preposition *at* in *the woman is at her desk* indicates not only that the woman is in close proximity to the desk (a topological-geometric relation), but that she is likely to be working there (an extra-geometric functional relation). Indeed, there is much empirical work showing that meaning of spatial prepositions across a range of languages involves the instantiation of both geometric *and* extra-geometric factors (e.g., Carlson-Radvansky & Radvansky, 1996; Coventry, Prat-Sala & Richards, 2001). However, how geometric and extra-geometric constraints combine is an open question. Regier and Carlson (2001) present a computational account, the attentional vector sum (AVS) model, which grounds the preposition *above* in a mechanism analogous to population vector codes in the neural model of Georgopoulos *et al* (1986). However, Regier and Carlson deal only with geometric computations over the visual scene.

We present a new computational model which attempts to deal with the spatial prepositions *in*, *on*, *over*, *under*, *above* and *below* and extends processing of the visual scene to include functional factors parasitic upon object knowledge. One possibility is that object knowledge can be used as a means of weighting parts of geometric processing, as is suggested by Regier, Carlson and Corrigan (in press). In contrast, Coventry and Garrod (in press) suggest that separate geometric and extra-geometric processes are operational in parallel, and come together in a situation model. Our approach introduces cognitive-functional constraints by extending Ullman's (1984) notion of visual routines to include operations on *dynamic* rather than static visual input (cf. Cavanagh *et al*, 2001). We use neuropsychologically-inspired implementations of connectionist models (cf. Regier, 1996). Based on evidence of motion and spatial-frequency processing in areas V1-V4, the MT, and interactions from regions implicated in object-recognition, such as the IT cortex (Edelman, 1999), we construct a model which might account for extra-geometric *and* geometric factors in one computational system. Developmental accounts of an infant's understanding of concepts such as geometry (spatial relations), dynamics (e.g. gravity, containment and object constancy), and object individuation and identification constrain the training of

relevant parts of our model. To give an example, the containing part of a mug is usually taken to be the part the liquid is poured into, and not the semi-circular handle. By watching interactions between mugs and liquids, we induce a dynamic visual routine, and a representation of the object over time. These routines and representations can then be deployed in future processing, for example, to generalize to similar objects *in the absence* of functional interactions. Initial results show that the computational model performs similarly to reference data, obtained from new experimental data on spatial preposition comprehension tasks.

A Basis for a Rigorous Cognitive Science: Maintaining Context for Information Exchange between Modules in a Functional Hierarchy

L. Andrew Coward (lacoward@dijkstra.murdoch.edu.au)
School of Information Technology, Murdoch University
South St., Murdoch, WA 6150 Australia

A functional system acts upon itself and an environment in order to achieve internally specified objectives. A system is defined as functionally complex if four conditions are met. The first is that the system can perform many different behaviours. The second is that the system has multiple potentially conflicting objectives. The third is that a high degree of interaction is required between large volumes of information derived from current and past environmental and internal system conditions, from past behaviours, and from system objectives in order to determine appropriate behaviour at any point in time. The fourth is that limited time is available between when an environmental condition occurs and when a behavioural response must be completed.

By this definition, electronic image processing systems are functionally trivial (although difficult to design). The vast majority of information technology applications are very simple functionally. Functionally complex electronic systems are those which control large physical systems with no human intervention except as users of services provided. Such physical systems include aircraft simulators and telecommunications networks. The corresponding electronic control systems have millions of lines of software code designed by hundreds of engineers. Brains are biological examples of functionally complex systems.

Experience with functionally complex electronic systems demonstrates the need for system architectures which make effective use of resources, allow functional changes without side effects, and permit identification and repair of failure conditions. Analogous needs exist for biological brains. These needs force any system which performs a sufficiently complex combination of functions into a modular hierarchy defined by the requirement that modules on each level are roughly equal and information exchange between modules is minimized as far as possible (Coward 2000; 2001). In addition, careful attention must be paid to maintaining the context for such information exchange. Modules within such a hierarchy will not in general correspond with obvious system features, but can be used to relate high level system functions to detailed operations down to the device level.

Two types of information exchange are possible between modules. An unambiguous information exchange indicates that the currently appropriate system behaviour is within a specified set of possible behaviours with 100% confidence, and can therefore be interpreted as an instruction. A partially ambiguous information exchange indicates that appropriate system behaviour is probably within a specified set of possible behaviours, and can therefore be interpreted as a recommendation (Coward 2001).

The requirement to support unambiguous contexts forces a system into the memory, processing form of the von Neumann (or instruction) architecture ubiquitous in

functionally complex electronic systems. However, heuristic definition of functionality (i.e. learning) is impractical with unambiguous information exchange.

The requirement to support meaningful although partially ambiguous contexts forces a system into the clustering, competition form called the recommendation architecture. Heuristic definition of functionality is possible, with clustering defining and detecting information combinations in system inputs and competition associating different sets of combinations with different behaviours. However, the requirement to maintain contexts is a severe constraint on both physical form and device algorithms (Coward 2000; 2001).

An implemented electronic version of a system with the recommendation architecture has demonstrated that learning is possible in such a system, and that learning can proceed with minimal effects on prior learning. There are a wide range of similarities between the structure and phenomenology of the implemented system and that of the mammal brain (Coward 2001).

The cortex with columns and areas resembles the clustering subsystem of the recommendation architecture, and the thalamus, basal ganglia and cerebellum resemble the required competition subsystems. REM sleep resembles the required process to ensure global minimization of information exchange. The phenomenologies of implicit and explicit memory resemble the different types of changes to information recording in clustering and competition (Coward 1999). The memory deficits introduced by damage indicate that the hippocampus manages resource assignment within the cortex (Coward 1990).

It is concluded that natural pressures have forced mammal brains into the recommendation architecture form, and that this architectural form can be used to understand the relationships between cognitive processes and physiology.

Dynamic Interrelations Among Processing Efficiency, Working Memory, and Problem Solving: A Longitudinal Study

Andreas Demetriou (ademetriou@ucy.ac.cy)

Department of Education, University of Cyprus
P.O. Box 20537, 1678 Nicosia, Cyprus

A study is presented aiming to contribute to the integration of the information processing, the differential, and the developmental modelling of the mind into a comprehensive theory. This is a longitudinal study which investigated the relations between processing efficiency, working memory and problem solving from the age of 8 to 16 years. This study involved 113 participants, almost equally drawn among 8-, 10-, 12-, and 14-year olds at the first testing: these participants were tested for two more times spaced one year apart. These participants were tested individually with a large array of tasks addressed to processing efficiency (that is, speed of processing and inhibition), working memory (that is, phonological storage, visual storage, and the central executive of working memory), and thinking (that is, quantitative, spatial, and verbal reasoning).

Confirmatory factor analysis validated the presence of all of the above dimensions and indicated that they are organized in a three-stratum hierarchy. The first stratum included all of the individual dimensions mentioned above. These dimensions are organized, at the second stratum, in three constructs, namely processing efficiency, working memory, and problem solving. Finally, all second-order constructs are strongly related to a third-order general factor. This structure is stable in time.

Structural equation modelling indicated that the various dimensions are interrelated in a cascade fashion so that more fundamental dimensions are part of more complex dimensions. That is, speed of processing proved to be the most important aspect of processing efficiency and it is strongly related to the condition of inhibition, indicating that the more efficient one is in stimulus encoding and identification, the more efficient one is in inhibition. In turn, processing efficiency is strongly related to the condition of executive processes in working memory, which, in turn, are related to the condition of the two modality-specific stores (phonological and visual). Finally, thinking was related to both processing efficiency and working memory, the central executive in particular.

These findings provide only partial support to the basic positions in psychometric theorizing

concerning the role of the components of processing capacity in the functioning of thinking. Specifically, none of these components alone is the crucial factor in the functioning of thinking. Rather, they additively contribute to its functioning. Moreover, a considerable amount of variance in different domains of thinking remains unexplained by these general factors. Therefore, any theory of intelligence must be able to account for the organization and functioning of these domains.

All dimensions appeared to change systematically with time. Growth modelling suggested that there were significant individual differences in attainment in each of these dimensions. Moreover, development affected differently each of them as well as their interrelation. Mixture growth modelling suggested that there were four types of developing persons, each being defined by a different combination of performance along these dimensions. Some types were more efficient and stable developers than others. These analyses indicated that processing efficiency is a factor that explains developmental differences in problem solving whereas working memory explains individual differences. Modeling by logistic equations uncovered the rates and form of change in the various dimensions and their reciprocal interactions during development. A developmental model is proposed to account for these findings.

Tutoring Real-Time Dynamic Task Performance: Using ADAPT to Augment Pilot Skill Acquisition

Stephanie M. Doane (sdoane@ra.msstate.edu)

Daniel W. Carruth (dwc2@ra.msstate.edu)

Engineering Research Center, Mississippi State University
2 Research Boulevard, Mississippi State, MS 39762 USA

Background

This research examines the role of comprehension-based cognitive processes in the acquisition of skills in real-time dynamic task environments. A theoretically-based model of pilot instrument flight (ADAPT) is used as the student model component (VanLehn, 1988) of an intelligent tool for training real-time complex task performance. ADAPT is a computational model of action-planning with an architecture based upon Kintsch's (1994; 1998) construction-integration theory of comprehension. ADAPT's learning mechanisms are used to model instrument flight skill acquisition (Doane, Sohn, McNamara, & Adams, 2000) and to select instructions intended to optimize pilot performance.

In previous research, rigorous tests of ADAPT's predictive validity compared performance of individual pilots to that of their respective models (Doane & Sohn, 2000; Doane, 2001; Sohn & Doane, 2002). Individual pilots were asked to execute a series of flight maneuvers using a flight simulator, and their eye fixations and control movements were recorded in a time-synched database. Models of the 25 individual pilots were constructed and used to simulate pilot execution of the same flight maneuvers. The time-synched eye fixations and control movements of individual pilots and their respective models were compared. The results suggest that the model explains and predicts a significant portion of pilot visual attention and control movements during flight as a function of piloting expertise.

Current Research

Current research is focused on incorporating ADAPT into a prototype training system that can identify training opportunities. In the training system, human pilots accomplish flight maneuvers using a graphical flight simulator. Their eye movements are tracked by an ASL oculometer and their control movements and flight performance are recorded by flight simulator software. The flight simulator and oculometer data are time-synched, passed to the ADAPT model for analysis, and then ADAPT selects instructions that optimize pilot comprehension of their current task environment.

Of particular interest for cognitive science is how ADAPT uses performance data to make inferences about individual pilot knowledge, skill, and focus of attention, and the ability of the model to run simulations in real-time to predict future pilot actions and to select instructions that

optimize future performance. Instructions will be delivered to pilots via agents that use verbal (e.g., voice instructions via earphones) as well as nonverbal forms of communication. The major challenge will be to accomplish this goal without disrupting pilot performance. We will measure subject response to instruction and the time course of their learning and relate these back to the a priori individual differences in pilot performance.

This research will make a theoretical contribution to our understanding of the role of comprehension-based cognitive processes in real-time complex and dynamic task performance. It will also make practical contributions to training technologies that can be used to augment the acquisition of complex task performance skills.

We have been developing learning environments with animated conversational agents. The agents manage a mixed-initiative dialog between the learner and the computer system either by a direct conversational interaction or by serving as a navigational guide on a web site. Two of the systems simulate human tutors by (a) presenting difficult questions that require deep reasoning, (b) attempting to comprehend the learner's typed input, (c) formulating dialog acts that are sensitive to the learner's contributions, and (d) speaking to the student with the animated agent. AutoTutor teaches computer literacy whereas Why/AutoTutor teaches conceptual physics (Graesser, VanLehn, Rose, Jordan, & Harter, 2001). The Human Use Regulatory Affairs Advisor (HURAA) teaches officers in the military about the ethical use of human subjects on a web site with a search facility that accesses documents through questions posed in natural language.

All three systems have used Latent Semantic Analysis (LSA) as its primary representation of world knowledge. LSA is a statistical technique that compresses a large corpus texts into a space of 100-500 dimensions (Landauer, Foltz, & Laham, 1998). The K-dimensional space is used when evaluating the similarity between any two bags of words, with values ranging from 0 to 1. From the standpoint of AutoTutor and Why/AutoTutor, one bag of words is the set of assertions that a student expresses within a dialog turn; the other bag of words is the content of the curriculum script

for a particular topic. From the standpoint of HURAA, one bag of words is the learner's query in natural language and the other is a paragraph in the document space. LSA has generally been successful in evaluating the quality of student explanations, in evaluating the quality of student assertions in tutorial dialog, and in the retrieval of documents from natural language queries. Successes and failures of LSA are identified in these three learning environments.

Human-Automation Interaction Strategies

Stephanie Guerlain (guerlain@virginia.edu)

Department of Systems and Information Engineering, University of Virginia
151 Engineers Way, Charlottesville, VA 22904-4747 USA

One approach to limiting the consequences of error-prone human performance is to automate as much as possible in a system. However, accidents and near-misses have occurred when automation fails to perform as desired, and the people "supervising" the automation have trouble determining the state of the automation, the state of the underlying process being controlled, or the implications of how changes to the state or to the automation parameters will affect overall performance. Other classic problems with automation include loss of human skill as tasks become automated and brittleness (the automation works well for the situations for which it is designed but can otherwise give up control or attempt a solution that is completely inappropriate).

Often, much effort goes into the design of computerized algorithms, but relatively little effort is put into the user interface. To design explicitly for *mixed-initiative interaction*, one needs to design a system where both the automation and the human operator have the capability to guide or perhaps even take over control of the system being controlled and that both the human and the automation each has the information and communication means necessary to make his/her, or its own "judgments" about the situation and to guide and perhaps critique the other's behavior. Clearly, due to the well-known differences between information systems' and humans' strengths, weaknesses, and means to: 1) sense information, 2) make judgments, and 3) execute actions, both the types of information required and the means for gathering and communicating that information will necessarily be different for each type of agent. Recent research has suggested certain strategies for safer automation design (assuming humans must monitor or guide the automation's behavior). These are:

1. Interactivity (allow humans to generate alternative automated and manual solutions, with the automation providing a comparison across all these solutions) (Guerlain, 2000).
2. Include user-initiated notification and critiquing. User-initiated notification (Guerlain & Bullemer, 1996) allows the human operator to set up temporary, context-sensitive "monitors" and to define who to be notified (person or system) and what to do when such conditions are met. These alerts can be process-specific, temporal, or a combination of the two. User-initiated notification can be turned into a critiquing strategy (Fischer, Lemke, Mastaglio, & Morch, 1990; Guerlain et al., 1999; Silverman, 1992) when these types of context-sensitive alerts are programmed in at design time (e.g., not by the operator, but by the engineer or knowledge expert), and are designed to be more generic and continuous monitors

for faulty or important conditions that are in general rare, but would require operator or automation attention.

3. Use appropriate representation aiding and workspace navigation techniques, to minimize errors and difficulties associated with excessive cognitive integration and to maximize effective decision making. The goal of representation aiding is to represent relevant domain, task, and system constraints through visual properties of the display, and thus encourage people to perceive these relationships with little cognitive effort. Workspace management refers to the window manipulation, command input, and navigation activities required when working with computer-based systems (Guerlain, Jamieson, Bullemer, & Blair, 2002).

These techniques have been successfully applied across diverse domains, such as petrochemical, medical, and military. These solution strategies are by no means foolproof, but they are as generic as the problem of how to design for safety when humans and automated agents are involved.

Statistical learning, implicit memory, and phonology

Prahlad Gupta (prahlad-gupta@uiowa.edu)

Department of Psychology, University of Iowa
Iowa City, IA 52242 USA

John Lipinski (john-lipinski@uiowa.edu)

Department of Psychology, University of Iowa
Iowa City, IA 52242 USA

This paper argues that (1) implicit memory is based on statistical learning; (2) phonological learning of word forms is based on implicit memory, and therefore that (3) phonological learning of word forms is statistical learning.

Implicit memory as statistical learning

A theoretical analysis of two key implicit memory phenomena, skill learning and repetition priming, shows that a number of apparent dissociations between them are misleading (Gupta & Cohen, 2002). First, it can be shown that the fact that skill learning but not repetition priming follows the power law of practice follows from the mathematical definitions of these constructs, and that this dissociation is therefore artifactual. Second, it can be shown that the presence or absence of correlations between these phenomena is also artifactual, and also follows from their definitions. Behavioral dissociations between these phenomena therefore cannot be regarded as evidence of a processing dissociation between them. Further, a statistical learning based computational model can be shown to account for specific empirical data, exhibiting a classic profile of skill learning and repetition priming, as well as a number of apparent dissociations between these phenomena (Gupta & Cohen, 2002). These theoretical and computational analyses provide complementary evidence that skill learning and repetition priming are aspects of a single underlying mechanism that supports implicit memory. The computational simulations suggest that this mechanism has the characteristics of statistical learning.

Phonological learning as implicit memory

The hypothesis that phonological learning of word forms is based on implicit memory predicts that implicit memory tasks employing nonwords (i.e., novel phonological word forms) should yield a typical profile of skill learning and repetition priming (e.g. Gupta & Dell, 1999). A typical multiple-repetition implicit memory task was devised in which participants were presented with nonwords. Some of the nonwords in each block of stimuli appeared only once during the experiment while other nonwords appeared in every block. Participants were simply required to repeat each stimulus as soon as it was presented. Performance functions were very similar to

those in standard implicit memory tasks, exhibiting classic skill learning and repetition priming. These findings suggest that implicit memory plays a role in the learning of phonological forms, which in turn suggests a role for statistical mechanisms in phonological learning.

Further evidence of the role of distributional statistics in phonological learning comes from a second manipulation in the study. If distributional statistics play a role in the learning of phonological word forms, then a word form's frequency-weighted neighborhood density (N) should impact repetition priming. To test this hypothesis, half of the nonword stimuli had a high N and half a low N . Neighborhood density was found to have a significant impact on learning of the nonwords.

Phonological learning as statistical learning

The effects of neighborhood density provide new evidence that phonological learning is affected by the distributional statistics of the environment. The presence of classic skill learning and repetition priming effects in nonword repetition provides complementary evidence regarding the nature of the underlying learning, suggesting it is based on implicit memory. The theoretical and computational analyses suggest that implicit memory is based on statistical learning mechanisms. Together the present results provide new evidence that learning novel phonological forms is based on statistical mechanisms.

Mental Visualizations and External Visualizations

Mary Hegarty (hegarty@psych.ucsb.edu)

Department of Psychology, University of California, Santa Barbara
Santa Barbara, CA 93106 USA

Recent advances in computer technology and graphics have made it possible to produce powerful visualizations of scientific phenomena and more abstract information. There is currently much excitement about the power of these computer visualizations in activities such as scientific discovery, search of information spaces, and education (e.g., Card, Mackinlay & Schneiderman, 1999; Gordin & Pea, 1995).

In this presentation I will define a visualization, very broadly, as any visual-spatial display in which information is communicated by the spatial arrangement of elements in the representation. Computer visualizations are often dynamic. However static graphs, diagrams and maps are also examples of visualizations. Visualizations often depict physical phenomena that are spatial in nature, such as the development of a thunderstorm. They can also depict more abstract phenomena, such as the flow of information in a computer program or the organization of information on the world wide web. A visualization can exist both internally, in the mind of an individual (as a mental image) or as an artifact printed on paper or shown on a computer monitor that can be viewed by an individual.

Whereas our ability to internally visualize has probably not changed significantly in recent history, technology has significantly improved our ability to create external visualizations. It is probably not surprising therefore that current research on the role of visualization in thinking focuses on external visualizations. Cognitive scientists have made important contributions to research on external visualizations (e.g., Larkin & Simon, 1987; Scaife & Rogers, 1996). There has also been an important tradition of research on internal visualization within cognitive psychology (e.g. Kosslyn, 1994). However, psychological research on internal visualization has been more concerned with the nature of the imagery system than in its role in thinking and reasoning

The purpose of this paper is to explore possible relationships between internal and external visualizations and their role in thinking and reasoning. One possibility is that external visualizations can substitute for internal visualizations. This view assumes that one person can create an external visualization of phenomenon, a second person can view that visualization, and as a result the second person will have the same internal representation as the person who created the visualization. If this were true, an external visualization could act as a "prosthetic" for people with poor spatial visualization abilities. A second

possibility is that external visualizations augment internal visualizations, that is, provide information or insights that are additional to those that can be provided by internal visualizations. For example, an external visualization might show a more complex process than can be internally visualized within the limited capacity of visual-spatial working memory. A third possibility is that the ability to internally visualize might be a requirement for comprehending and using external visualizations. In this case, gaining insight from a visualization would depend on the same skills as internally visualizing. A fourth possibility is that viewing external visualizations enhances the development of internal visualization abilities. These possibilities are not mutually exclusive.

This paper will be informed by my research on mental animation of static diagrams (Hegarty, 1992) and on learning from animated displays (Hegarty, Narayanan & Freitas, 2002). It will discuss implications for education and training.

Holt (2001) proposed developing Scientific Information Systems to construct and validate theory concerning complex multi-person systems. Holt described a process of successive cycles of theory refinement using information in databases. Holt, Boehm-Davis, and Beaubien (2001) discussed the development of theory for describing crew performance in the aviation domain by statistically analyzing performance measures. These inductive, theory-building approaches require good data and analyses. Unfortunately, obtaining good quality measures may be difficult in domains such as aviation which are complex, dynamic, and multi-person (Holt, Johnson, & Goldsmith, 1997; Holt, Hansberger, & Boehm-Davis, in press).

An alternative approach is to carefully extend theory from a field closely related to the focus of research and subsequently validate it. This study was focused on aviation crew performance using flight deck automation during the descent phase of flight. The theory that was extended to this domain was the ACT-R 4.0 cognitive architecture (Anderson & Lebiere, 1998). The ACT-R architecture was extended to describe the highly procedural nature of crew performance in this context (e.g. checklists, Standard Operating Procedure, etc.). The initial development of this model focused on an ACT-R model of the Pilot Flying (PF) who had to receive directives from Air Traffic Control (ATC), decide on how to use the automation to achieve flight goals, and monitor the success or failure of actions.

Based on lessons learned from this initial effort, the approach was extended to constructing a crew model with a simulated PF and Pilot Not Flying (PNF). These crew members were simulated by separate ACT-R models based on a cognitive task analysis of the duties for each person. The simulated task scenario was the time period just before and after Top of Descent (TOD) in the descent phase of flight. The PNF tasks included verification and programming of the Flight Management System (FMS) computer as well as gathering appropriate information for completion of the flight. The PF monitors and flies the aircraft except for required briefings and responses.

Required aspects of crew interaction such as crew communication (e.g. briefings, acknowledgments) were implemented by a communication link between the PF and PNF simulations using a multi-model extension of ACT-R. Simulated communications involved goals, specific actions, or situational facts and features.

The linked PF and PNF models were evaluated by manipulating the simulated expertise of the crew. Expertise

was simulated by changing ACT-R parameters and structures. Specifically, higher expertise was simulated by combinations of high strength of associative links for procedural behavior, higher working memory capacity, and cognitive strategies such as the systematic reactivation of goals cued by external stimuli such as a checklist.

One advantage of using the cognitive architecture was that a complete profile of cognition and performance could be measured for each simulation run. Model performance measures include total time for all tasks, average time for each task, checklist steps skipped, repeated, or performed out-of-order, automation programming delayed, skipped, or incorrect, and the omission of required communications.

Qualitative results such as step skipping, repetition, and intrusion of incorrect steps were observed at lower levels of simulated expertise. Emergent results included crew miscommunication, differential situation awareness, and forgetting relevant goals under certain conditions of delays and interruptions. The precise profile of performance differences for different levels of crew expertise can be used to develop assessment items, strategies, and guidelines for assessing performance of commercial crews.

Promoting Transfer through Case-Based Reasoning: Rituals and Practices in the Learning by Design Classroom and Evidence of Transfer

Janet L. Kolodner (jlk@cc.gatech.edu)

College of Computing, Georgia Institute of Technology
801 Atlantic Drive, Atlanta, GA 30332-0280 USA

Our goal in education is to help students learn content and skills in ways that allow them to use what they are learning in new and novel situations. We want them to learn for transfer. The cognitive literature focuses on the cognition, or individual reasoning, needed to learn for transfer (see, e.g., Bransford et al., 1999). The socio-cultural literature focuses on the social interactions that are important for learning skills and practices in such a way that they can be performed in new and different contexts (e.g., Lave & Wenger, 1991). Both agree the building blocks for engaging in skills and participating in practices in an expert way are developed over time and in stages and require a variety of experiences and reflection on them. The computational models of cognition that come out of case-based reasoning (CBR; Kolodner, 1993) allows us to redefine transfer as spontaneous reminding and use of previous experience in reasoning about a new situation (Kolodner et al., 2002). This interpretation of transfer suggests practices for the classroom that can promote transfer (Kolodner, 1997).

We've designed a project-based inquiry approach to science learning for middle school called Learning by Design" (LBD"; Hmelo et al., 2000; Kolodner et al., 1998, 2002), based on these principles. We've identified many of the affordances and potential affordances for transfer that project and problem-solving activities provide, and we've designed classroom rituals and practices that help teachers and students identify those affordances and act on them. In science education, there is a need for students to learn not only content but also the skills and practices of scientists — from measuring and observing to interpretation of data to justifying with evidence and explaining causally to communicating with others, planning investigative activities, and applying what's been learned. LBD focuses on helping students learn this full set of objectives.

CBR tells us that productive learning from experience requires timely feedback on one's experiences, interpreting that feedback and explaining what happened in light of one's goals and intentions, making connections between one's goals, plans, and explanations, and having the chance to try again. It emphasizes the iterative nature of learning and the centrality of explanation. LBD's activity structures and sequencing provide both affordances and scaffolding for such reasoning. Students learn within the context of design challenges that require iterative trial and refinement for achievement. It is also highly collaborative. They engage in a variety of public presentations (poster sessions, pin-up sessions, and gallery walks) where they present their ideas, interpretations, and experiences to their peers in an interactive forum. Preparing for a session requires making

connections between one's goals, plans, and explanations. The public venue allows students to get help from their peers at explaining their results. It also provides students with a variety of examples that are then discussed with lessons that might be learned from the full set extracted. As they iteratively move toward better design solutions, they iteratively enhance their understandings of concepts and their abilities to engage in skills and practices.

Students spontaneously make reference to previous experiences over the course of several months of engaging in LBD activities, especially with respect to carrying out skills and practices. Our performance assessments show spontaneous reminding and use of both knowledge and skills, and LBD students are more capable than comparison students of engaging as scientists and collaborators (Kolodner et al., 2002). We propose that studying learning environments that encourage the natural use of case-based reasoning will increase our understanding of transfer.

Dynamic Adaptation to Critical Care Medical Environment: Error Recovery as Cognitive Activity

Tate T. Kubose (kubose@dm.columbia.edu)

Vimla L. Patel (patel@dm.columbia.edu)

Desmond Jordan (daj3@columbia.edu)

Department of Medical Informatics, Columbia University
622 W. 168th St. VC-5, New York, NY 10032

Introduction

Early research on errors focused on studies of human reliability in engineering domains. Human components were considered as additional elements in the system, similar to other technical components. Just as technical safety is improved through the reduction of technical breakdowns, it seemed common sense to use a symmetrical rationale to improve safety through the reduction of human errors. In the last few years, Patel and colleagues have reported a number of studies that focused on understanding dynamic decision making in high velocity medical environments, namely intensive care and medical emergency units (Patel and Arocha, 2000; Patel, Kaufman, and Magder, 1996). These and other studies have identified the problems of post-hoc analysis in research on error detection and faults in such environments, that are characterized by high levels of urgency, uncertainty, and shifting, ill-defined, and competing goals. Although such investigations into human error sometimes necessitate a post-hoc analysis, and can be very informative in identification and reduction of future errors, such retrospective analysis presents several problems.

Methodology

The data were collected in the cardiothoracic intensive care unit at a large teaching hospital using naturalistic approaches. The methods used represent an extension of the information-processing, cognitive science tradition. In order to examine the nature of the interactions and negotiations occurring within the workflow of the ICU, we performed approximately four months of ethnographic observation to collect data about the employees and general workflow of the ICU. We then shadowed three nurses for the duration of their 12-hour shifts. During shadowing, we followed the nurse wherever they went, audio-recorded their conversations with other ICU team members, and took notes in a journal to record non-verbal activities. The audio-tapes were transcribed for later analysis.

Results

The data provided us with information about the daily patterns of communication within the ICU and insight into the professional and social relationships between staff members in conducting daily activities. Through protocol analysis of the transcriptions, we were able to characterize specific instances of errors made and circumstances which

are highly susceptible to such errors. While many errors occurred, most of them were often detected and resolved very quickly, either through (1) communication between team members or (2) feedback from the ICU environment. For instance, continued use of a sedative to deal with patient pain was quickly rejected as a treatment plan when one team member realized that it was contributing to liver failure. While one ICU staff member alone may have missed this error, with it perhaps leading to an adverse event, the ICU team was able to, through their interactions, identify the potential for error and take steps to prevent it. Although this situation was managed with error recovery, instances such as these can be missed and contribute collectively to more serious errors.

Discussion and Conclusion

We suggest that mistakes are an inevitable, cognitively useful phenomenon that cannot be totally eliminated. We view human errors as products of cognitive activity regulated in a broader context of adaptation to one's environment and work activities. In this view, where human activity is seen as dynamic adaptation to the work environment, most errors can be considered as the price paid for making compromises in trading off between various alternatives. Unlike the popular goal of achieving flawless performance (through development of error-free systems), our study argues for developing systems that are adaptive enough to allow for the specific nature of human errors.

Acknowledgments

This research was funded by US Army Grant #2000-36-U-of-Texas. We would like to extend our warmest gratitude to the nurses and doctors of the ICU, especially to the three nurses who shared an entire day of their lives with us.

Applications of Latent Semantic Analysis

Thomas K Landauer (landauer@psych.colorado.edu)
University of Colorado at Boulder, CB 344 Boulder, CO 80309
and Knowledge Analysis Technologies, LLC

Latent Semantic Analysis (LSA) treats language learning and representation as a problem in mathematical induction. It casts the passages of a large and representative text corpus as a system of simultaneous linear equations in which passage meaning equals the sum of word meanings. Solution by Singular Value Decomposition (SVD) and dimension reduction produces a high-dimensional vector representing the average contribution to passage meanings of every word, and thus of the similarity between any two passages. LSA simulates human language understanding with surprising fidelity. Combining LSA with other statistical language modeling methods increases its practical scope. A variety of tests and applications illustrate its power, limits, and raise interesting theoretical issues.

Examples from Previously Published Results

LSA Improved IR 10-30% by recognizing documents of similar meaning but different words (Dumais, 1991); powered automatically constructed cross-language information retrieval (Landauer and Littman, 1990); mimicked the 10 words/ day vocabulary acquisition rate of children (Landauer & Dumais, 1997), and college student learning of psychology from textbooks (Landauer, Foltz & Laham, 1998) as measured by multiple-choice tests; simulated human categorization and similarity ratings (Laham, 2000), enabled simulations of predication and metaphor. (W. Kintsch, 2001); predicted paragraph comprehension differences caused by variation in S-S coherence; predicted which texts students would learn most from as a function of their prior knowledge (Rehder et al.; Landauer, Foltz & Laham, 1998); and improved summarizing skills by automatic componential feedback (E. Kintsch & Steinhart, 2000).

New Tests, Advances and Applications

LSA now scales to ca. 100 million word corpora by larger computer memory and new algorithms. Systems based on LSA measure the quality of sentences written to contextually define a word, $r = .81$ with expert ratings; connect by conceptual meaning each of a million paragraphs of an e-library; power collaborative learning environments that automatically alert participants to relevant contributions of others and assess contributions; enhance technical manuals to improve learning and speed performance; from text about tasks, occupational histories, etc., help guide career choice, fill jobs, and assemble optimal teams; combined with other statistical

language models, score essays as accurately as expert human readers and provide componential feedback and plagiarism detection.

Some Implications, Limitations, and Issues

Successes to date disprove the poverty of the stimulus argument for lexical meaning and recast the problem of syntax learning, but leave much room for improvement. Size matters. The largest text corpora used in these applications equals one student's reading through high school; spoken language experience is an order of magnitude greater. Semantic atoms are not only single words; idioms need lexicalization. Syntax surely matters; LSA ignores word order. LSA's knowledge resembles intuition; people also use language for logic. Relations to other input matter. Perceptual and intentional experience contribute to meaning representation. (However, whether these bases are essential, more fundamental or involve different representational mechanisms is an open question. LSA represents perceptual phenomena vicariously, e.g. color relations. Demonstrations that people think in other modes, or that LSA does not exhaust linguistic meaning do not question LSA's validity, but call for more modeling, testing, and integration.

Possible Avenues for Research and Resolution

Similar inductive methods have been applied in perception (e.g. by S. Edelman, 1999), opening a road to integrating language and perception. New models with learning of sentential order based meaning are needed. Simon Dennis's new unpublished model is a serious contender.

Modeling the Development of Lexicon with DevLex: A Self-Organizing Neural Network Model of Lexical Acquisition

Ping Li & Igor Farkas (pli, ifarkas@richmond.edu)

Department of Psychology, University of Richmond, Richmond, VA 23173, USA

It is well known in developmental psycholinguistics that young children produce a significant amount of speech errors at a certain stage, which is often associated with U-shaped learning (Bowerman, 1982). Not only do children show errors in morphological development (e.g., the well-known past tense errors), they also display errors in word naming and in spontaneous word production. Various accounts have been offered for these errors, from the child's confusion of related semantic fields, to the child's semantic reorganization, to the child's inability to retrieve the correct items in lexical memory during production. In this study, we investigate the nature and origin of these errors as a function of the organization and reorganization of a developmental lexicon, using DevLex as the basis of our modeling.

DevLex is a self-organizing neural network model that has the following properties (Farkas & Li, 2002). The model consists of two self-organizing maps interconnected by associative links. The two maps attempt to capture the organization of word meanings (the semantic map) and word pronunciations (the phonological map). The semantic map is a dynamically growing network that learns word representations derived from word cooccurrence matrices in child-directed speech. It organizes word representations incrementally, adding new units to areas with higher lexical density. Semantic map is connected with phonological map that is pre-trained on the PatPho representations (Li & MacWhinney, 2002) of the 550 toddler word-list from the CDI lexical norms (Dale & Fenson, 1996). At every iteration during simulation, the semantic and phonological representations of words are simultaneously presented to both maps. Through self-organization (using Kohonen's algorithm), the network forms an activity on the phonological map in response to the phonological input, and an activity on the semantic map in response to the semantic input. For every word being presented, the model simultaneously learns associative connections between the two maps through Hebbian learning. DevLex is evaluated with respect to its accuracy in semantic representations and in productions (via associative connections from semantics to phonological output).

Our simulation results indicate that DevLex is able to model and provide insights into a range of phenomena in the early lexical acquisition. In particular, the onset of errors (measured as number of words confused in the network) reflects a number of important factors that govern lexical development. (1) The lexical categories of nouns, verbs, adjectives, and closed-class words have different profiles over the course of lexical growth, and their relative proportion, type frequency, and token frequency all affect the kinds of errors made in the network. This finding confirms Bates et al's (1994) argument on the important role that word category composition plays in lexical acquisition.

(2) Number of words confused in the semantic map and in production is directly related to word density, measured as the amount of words mapped onto the nearest neighborhood of the target word. In addition, lexical confusion occurs more often for nouns than for other word categories, because of a "noun-bias" in the early vocabulary. This result shows that the source of children's naming errors may be the tight competition among similar neighbors in densely populated regions of the lexicon, consistent with the view that word density can predict the speed and accuracy in children's lexical access (Charles-Luce & Luce, 1990). (3) The rate of vocabulary expansion influences the rate of lexical confusion: the more related words that the network has to learn within a given period, the more likely it will show inaccuracies in the semantic map and in production. This pattern is consistent with the hypothesis that rapid increase in the rate of new words predicts the increase in children's naming errors (Gershkoff-Stowe & Smith, 1997). In sum, DevLex provides a new connectionist model that can simulate a developmental lexicon and relate to realistic language learning with self-organizing principles.

Where Do Problem-Solving Strategies Come From?

Marsha C. Lovett (Lovett@cmu.edu)

Department of Psychology, Carnegie Mellon University
5000 Forbes Avenue, Pittsburgh, PA 15213 USA

Research has shown that people often generate problem-solving strategies in a new domain by processing example solutions. However, this approach presumes the existence of some related strategies for processing examples in that new domain. The question then becomes: Where do *those* strategies come from? An important aspect of processing examples is knowing which features of the example problems are structurally significant and which features are superficial. Indeed, much research on expert-novice differences highlights experts' great advantage in properly representing and categorizing problems in terms of deep features (e.g., see Chi, Glaser, & Farr, 1988). But how can problem solvers new to a domain achieve this skill? In many domains, solvers have preconceptions of which features are significant and which are superficial. When these preconceptions are on target, i.e., the presumed-significant features are indeed relevant to the solutions and the presumed-superficial features are irrelevant, then learning by example can proceed effectively and efficiently. However, when solvers' preconceptions do not match reality for a given domain — either because their preconceptions mis-map features to the significant-superficial distinction or because their preconceptions are too weak to enable encoding of the relevant features — then learning is impeded.

Background Research

In previous work, Lovett and Schunn (1999) demonstrated that the same task with different superficial features could lead participants to generate very different strategies and, depending on their individual strategies, achieve very different learning gains. Specifically, in one version of the task, participants tended to encode their choices in terms of a single feature — whether each choice had the same color as the preceding stimulus — whereas in the other version of the task, participants were not biased to any particular feature. The experiment was then designed so both task versions would be best solved using a common, structurally important feature, and this was *not* the same-color feature salient in version 1. As predicted, performance was degraded in version 1. This was attributed to the difficulty — for participants in version 1 — of learning to ignore a preconceived-relevant feature and having to generate new strategies that did not use this feature. Lovett and Schunn presented a process model, called ReCyCLE, of how features enter and leave one's task representation and, hence, how strategy sets evolve. One prediction of the ReCyCLE model is that solvers are more likely to change their representation when their current strategies' success rates are low.

Goals and Method

The current studies attempt to replicate this previous work under slightly different conditions and to address two additional questions:

- (1) What, if any, are the local triggers for problem solvers to change their representations and generate new strategies?
- (2) What is the role of explicit instruction (e.g., hints) in helping solvers to adjust their strategy sets?

Question (1) was addressed by asking a subset of participants to provide talk-aloud protocols and comparing coded occurrences of strategy-generation or strategy-change events to similar profiles among the non-protocol participants. Question (2) was addressed by manipulating if, when, and how participants would receive a textual hint about important features to include/exclude in their representation of the task. Also varied in this experiment was the degree of success of the best strategy. In particular, the best strategy's success rate could be increased/decreased by decreasing/increasing the overall randomness of the task environment. This manipulation is, simply construed, a task difficulty manipulation.

Results

Regarding the first question, results suggest that, at least when they are asked to talk aloud, participant engage in a considerable amount of explicit strategy (or hypothesis) generation. And, while participants tend to launch anew strategy immediately following a problem-solving failure rather than success, this is not always the case. Regarding the second question, results suggest that, when solvers mis-map features (i.e., when they consider the superficial features in a domain to be significant and vice versa), an explicit hint can help problem solvers more quickly incorporate the structurally important task features in their representations and strategies. Even with such hints, however, performance is still aided by further problem-solving practice. The instructional implications of these results will be discussed.

Is There a Decision Bias For Information From Internally Consistent Sources?

Shenghua Luan (herome@ufl.edu)

Department of Psychology, University of Florida
P.O. Box 112250, Gainesville, FL, 32611 USA

Robert D. Sorkin (sorkin@ufl.edu)

P.O. Box 112250, Gainesville, FL, 32611 USA

Jesse Itzkowitz (itz@ufl.edu)

Department of Psychology, University of Florida
P.O. Box 112250, Gainesville, FL, 32611 USA

A person faced with a decision often obtains opinions from other sources. These information sources may be composed of several individual sub-sources. The sub-sources may be partially correlated and may differ in their level of expertise.

This study asked how decision makers weigh the estimates received from different sources when those sources varied in their internal consistency and individual expertise. We paid people to perform a graphical decision task while aided by simulated information sources. Each participant observed a graphical display of a signal-plus-noise or noise-alone event and made an estimate of signal likelihood. The participant then was shown likelihood estimates generated from two simulated information sources. The participant then made a yes-no decision about the occurrence of signal on that trial. A monetary payoff was contingent on the accuracy of this yes-no decision.

The estimates from each information source consisted of likelihood ratings generated by four sub-sources. Thus, on each trial the participant was shown 8 likelihood estimates to aid in her decision, four estimates from information source "A" and four estimates from information source "B". In order to estimate the decision weight that the participant gave to each source, we constructed a multiple linear regression model that related the participant's initial estimate and each source's average estimate, to the participant's final decision.

In different conditions of the experiment, we manipulated the overall information value of a source and the level of expertise and pair-wise correlation among a source's sub-sources. Source expertise was manipulated using the following formula adapted from Sorkin and Dai (1994):

$$d'_{source} = \left[\frac{m\sigma_{d'}^2}{1-\rho} + \frac{m(\mu_{d'})^2}{1+\rho(m-1)} \right]^{1/2}$$

where d'_{source} is the detection index (aggregate expertise) of the source, m is the number of sub-sources in the group, ρ is

the correlation among the sub-source estimates, $\sigma_{d'}^2$ is the variance of the sub-sources' expertise and $\mu_{d'}$ is the average detection ability of those sub-sources.

For example, one condition tested which of two equal-information sources (i.e., two sources that have the same overall detection ability, d') would be given the higher weight: the one whose four sub-sources had partial pair-wise correlations and high sub-source d 's, or the one whose four sub-sources had zero pair-wise correlation and lower sub-source d 's. The results indicated that participants gave a significantly higher weight to the information source that had the higher consistency and higher component expertise, even though the information available from the two sources was identical. This bias was mainly evident on trials when the aggregate opinions of the two sources disagreed. Other conditions compared performance with sources that had different overall information values as well as different levels of sub-source expertise. In these conditions, the participants tended to overweigh the information from the sources having the higher information value and higher level of sub-source expertise. These biases reflect the participants' sensitivity to across- and within-trial differences in the accuracy and internal consistency of information sources.

Understanding and Scaffolding Constructive Collaboration

Naomi Miyake and Hajime Shirouzu

{nmiyake, shirouzu}@sccs.chukyo-u.ac.jp

School of Computer and Cognitive Sciences, Chukyo University
101 Tokodate, Kaizuchō, Toyota, 470-0393 JAPAN

Collaborative situations have started to serve as promising knowledge-building environments. Cognitive science should provide theoretical bases for them, by explaining mechanisms of how collaboration leads the participants to deeper, more conceptual understanding.

Findings of empirical studies

Our previous studies (e.g. Miyake, 1986) indicate that during constructive interaction, 1) each participant's problem interpretation and solution paths are based on each individual's prior knowledge, 2) collaboration provides different perspectives, through both others' comments and self-criticisms, and 3) the monitor views the task-doing situation from a slightly abstracted plane, which contributes to the accumulation of different perspectives.

To expand these, we have recently further analyzed the collaborative process of solving a simple fraction problem (Shirouzu, et al, 2002). The task was to get two-thirds of three-fourths on a square sheet of origami. More than ninety percent of time the subjects, both solos or pairs, either folded or marked the paper to solve it but did not calculate. When asked to solve the subsequent problem with the order of fractions reversed, the solos kept the same strategy to solve.

However, more than sixty percent of the pairs shifted to the arithmetic calculation in their second trial. The shift was a gradual one, involving three re-interpretations. Figure 1 schematically shows the shift, from the left to right. The most externally oriented, two-step strategy requires first folding the paper into four. Upon doing this, one could either start making two-thirds, or re-interpret the just-completed three-fourths as already having three equal-size rectangles, which eliminates the physical necessity of second folding. Similarly, one could re-interpret the two-thirds of the designated three-fourths as two-fourths of the original square. Re-interpreting this as one-half often led our pairs to realize that the problem was soluble by calculation.

Fig. 1 Gradual re-interpretation of getting $2/3$ of $3/4$.

Furthermore, it was the monitor who re-interpreted, for 100% of time from level 1 to 2, and 60% from level 2 to 3.

Supporting constructive collaboration

Based on these observations, we propose that the basic components of constructive collaboration are the externalized traces of the task-doer's cognitive workings and their re-interpretations by the monitor, in verbal forms. In verbalizing the re-interpretation, the monitor reclaims the

task-doing, on traces of which the previous task-doer can monitor to produce yet another level of abstracted verbalization. This iterates and produces a variety of re-interpretations, which each individual can use to restructure their own internal knowledge. The same picture should apply to inter-group collaboration, where the re-interpretation could be accumulated and become a resource for further abstraction in the entire community.

Summarizing the above, for a collaborative situation to work as a learning-enhancing environment, it is desirable that 1) it assures each individual's conceptual foundation, 2) it entertains the role exchange between task-doing and monitoring to help produce different solutions and their re-interpretations, all slightly more abstract than the previous ones, in roughly the order of their abstraction, 3) which in turn helps each participant to gain an abstract perspective. The social aspect of collaboration appears to motivate the integration of such a variety of solutions and interpretations.

Technological augmentation

Technology can augment implementation of these conditions by providing support to enhance externalization and re-interpretation. To take a simple example, the process of reading can be made visible by having subjects place cards with sentences onto a two-dimensional space. Video-recording of first stages of learning complex skills can be cut into segments and commented on to identify necessary steps. Notes can be shared, and the memos and linkages among them can be stored in the chronological order of their production, so that the production process itself can become a target for later scrutiny. We have been developing and testing such systems, and the context to use them, in a university setting to teach cognitive science to undergraduates (Miyake, et al., 2000; 2001). Use of such systems inevitably changes the way we teach and the students learn, requiring new methods to assess the effects and providing us with a new resource for further research on real-world understanding.

Learning from Worked-Out Examples via Self-Explanations: How it Can(not) be Fostered

Alexander Renkl (renkl@psychologie.uni-freiburg.de)

Department of Psychology, Educational Psychology, University of Freiburg
Engelbergerstr. 41, D-79085 Freiburg, Germany

Learning from worked-out examples is of major importance for initial skill acquisition in well-structured domains such as mathematics and physics. However, only those learners who actively explain the rationale of the solution steps presented in the examples to themselves profit from this learning method ("self-explanation effect", Chi, Bassok, Lewis, Reimann, & Glaser, 1989). Unfortunately, most learners are to be characterized as passive or superficial self-explainers (Renkl, 1997a). From an educational perspective, two main questions arise: (1) How can productive self-explanations be fostered? (2) When should instruction move from the self-explanation of worked-out steps to actually solving problems for heightened speed and skill accuracy? Both of these questions were addressed in a series of experiments.

With regard to fostering self-explanations, four issues were investigated: (a) Setting situational incentives: The main idea was that if most learners do not spontaneously generate elaborated self-explanations, it might be helpful to put them into the role of a tutor for another learner. This should motivate them to increase their explanation activities (e.g., Renkl, 1997b). (b) Training and prompting: Self-explanation activities can be induced by a training or by prompting self-explanations at worked-out steps (Renkl & Atkinson, in press; Renkl, A., Stark, R., Gruber, H., & Mandl, H., 1998). (c) Support by instructional explanations: A number of studies have shown that it is difficult to provide effective instructional explanations during example study. However, on the other hand, relying only on self-explanations also has some restrictions (e.g., proneness to errors). Therefore, a set of principles highlighting how to effectively support example study by instructional explanations was developed and empirically investigated (Renkl, in press). (d) Structuring learning materials: Learning materials (i.e., examples and problems) can be designed in order to induce active and well-focused self-explanations, for example, by giving the learner the opportunity of problem-solving experiences before example study (Stark, Gruber, Renkl & Mandl, 2000). The main findings of a series of experiments on these issues can be summarized as follows. The setting of situational incentives has shown not to be very promising. The training and prompting as well as designing learning materials can substantially foster self-explanations and, thereby, learning outcomes. In addition, well-designed instructional explanations can further enhance learning.

For structuring the transition from example study in early phases of skill acquisition to problem solving in a later stage, we developed a fading rationale by which problem-solving elements are successively integrated into example study until the learners are able to solve problems on their

own. The effectiveness of fading has been shown in several experiments (Renkl, Atkinson, Staley, & Maier, in press). Presently, we adapt the fading procedure to the learners' prior knowledge level.

Based on the results of our experimental research program, an instructional model of acquiring skills from examples and problems is proposed. It is argued that different learning goals are to be achieved in subsequent stages of skill acquisition (e.g., understanding vs. automation). Therefore, instruction should induce different learning activities during the course of skill acquisition. How these activities can be instructionally fostered can be derived from our experimental findings.

Category Use: Learning and Understanding Categories

Brian H. Ross (bross@s.psych.uiuc.edu) and Seth Chin-Parker (chinpark@s.psych.uiuc.edu)

Beckman Institute and Department of Psychology, University of Illinois
405 N. Mathews Ave., Urbana, IL 61801 USA

Categories are crucial for a large number of cognitive activities, such as classification, inference, problem solving, and explanation. They provide an important means for allowing us to benefit from past experiences. Because of this importance and involvement across a wide variety of intelligent activities, category learning has long been a central research topic in cognitive science, cognitive psychology, and machine learning.

Most of the research on category learning has focused on classification learning, how to assign items to categories. Although classification is an important part of category learning, it is clearly not the only part. In addition, this near-exclusive focus may be limiting our understanding in at least three ways. First, we learn categories in many different ways and how we go about learning categories is likely to have a large influence on what we learn. Thus, a full understanding of category learning requires examining multiple ways of category learning. Second, the focus on classification has led to finding a strong influence of feature diagnosticity, those features that distinguish the categories being learned. Although diagnosticity is an important influence on category representation, we clearly know much more about categories than what distinguishes them. However, given that many items consist of a large number of features and relations that might not be very diagnostic of the category, how do we determine what information to include or not to include in a category representation? Third, in many cases our knowledge of categories does not rely solely on observable features and relations, but on deeper underlying similarities of why the category members go together. It is not clear how classification learning promotes the learning of this type of category understanding.

Recently, there has been a variety of research examining the different ways people learn and use categories (for reviews see Markman & Ross, 2002; Solomon, Medin, & Lynch, 1999), which addresses these limitations of the focus on classification. First, studies have investigated how different ways of category learning might influence the representation (e.g., Anderson, Ross, & Chin-Parker, 2002; Yamauchi & Markman, 1998, 2000). Second, work has examined how nondiagnostic information relevant to other uses of categories might be learned when the focus is not on classification (Chin-Parker & Ross, 2002a, b; Ross, 1997, 1999). Third, research has begun to investigate the understanding that derives from using categories in different ways. Some of my work has examined category learning during problem solving with three different types of tasks—decoding formulas applied to coded messages,

mathematical equations, and letter-string transformations (e.g., Ross, 1997, 1999; Ross & Warren, 2002). The results suggest that not only can such learning lead to additional (nondiagnostic) information in the category representation, but it also allows the learning of abstract relations that may help learners to understand the underlying coherence among category members. For example, in the decoding task, learners are able to classify later coded messages on the number relations learned during decoding, even when the relations are fairly abstract (such as the difference between two numbers being less than zero).

Relating Properties of Human Memory to Cortico-Hippocampal Architecture

Lokendra Shastri (shastri@icsi.berkeley.edu)

International Computer Science Institute

1947 Center Street, #600; Berkeley, CA 94704 USA

Introduction

Episodic memory (Tulving, 1995) refers to our ability to remember events and situations in our daily lives and acquire memories of specific events by reading a newspaper or watching a newscast. There is a broad consensus that the hippocampal system (HS) consisting of the hippocampal formation and neighboring cortical areas in the medial temporal lobe plays a critical role in the encoding and retrieval of episodic memories (Squire, 1992; Cohen & Eichenbaum, 1995; Nadel & Moscovitch, 1997). But how the HS subserves this mnemonic function in concert with cortical circuits is not fully understood.

Although a number of computational models have been proposed to explain how the HS might support episodic memory function, several key representational problems have remained unsolved. In particular, most existing models view an item in episodic memory as a *feature vector* or as a *conjunctive code* that binds together the components of memory, but as argued in (Shastri, 2002; 2001), such a view is inadequate for encoding events and situations.

SMRITI

SMRITI (System for memorizing relational instances from transient impulses) is a computational model of episodic memory that demonstrates how a cortically expressed transient pattern of activity representing an episode can be transformed rapidly into a persistent and robust memory trace in the HS as a result of long-term potentiation (Shastri, 2001; 2002).

SMRITI explicates the representational requirements of encoding events and situations, proposes a detailed neural circuit that satisfies these requirements, and demonstrates that the propagation of a suitable pattern of activity encoding an event can lead to the rapid and automatic formation of the requisite neural circuit within the HS.

The neural circuit required for encoding an episodic memory trace is fairly complex and idiosyncratic, but SMRITI shows that this complexity and idiosyncrasy is well matched by the complexity and idiosyncrasy of the architecture and local circuitry of the HS.

Predictions and Explanations

SMRITI predicts (i) the functional role of each HS component and some of the cortical areas interacting with the HS, (ii) the properties of cortically expressed event schemas underlying episodic memories, (iii) the sorts of memories that must persist in the HS for the long-term, (iv) the nature of memory consolidation, and (v) memory deficits that would result from cell loss in different HS regions and cortical circuits encoding semantic knowledge.

SMRITI also offers biologically grounded explanations of behavioral findings about human memory such as the fan-effect (Anderson, 1974) and the list-strength effect (Ratcliff, Clark, & Shiffrin, 1990). It is significant that no attempt was made to model these behavioral findings; the explanations for these phenomena arise directly from the biologically grounded architecture and structure of the model.

SMRITI makes specific behavioral predictions about the time required for retrieving memorized facts. For example, it predicts that the time to retrieve a fact, wherein an entity fills a given role, is affected primarily by the total number of facts memorized in which the entity plays the same role, and not by the total number of facts memorized about that entity. Thus SMRITI suggests a modified form of the fan-effect. SMRITI also predicts that retrieval times of facts pertaining to populated event schemas are qualitatively different from those of facts pertaining to unpopulated ones. Here, an event schema is heavily (lightly) populated if many (only a few) instances of the schema have been memorized.

This talk will present an overview of SMRITI, and discuss some of its key properties and predictions.

What Happened to the Imagery Debate?

Peter P. Slezak (p.slezak@unsw.edu.au)

Program in Cognitive Science, University of New South Wales
Sydney NSW 2052, AUSTRALIA

Déjà Vu All Over Again?

Zenon Pylyshyn's (2002) recent return to the fray means that at least one thing may be said with certainty about the imagery debate: Despite Kosslyn's (1994) claim to have resolved the controversy, there has been no progress at all. Worse still, if Pylyshyn's null hypothesis is right, we don't have a viable theory of imagery of any kind. The 'tacit knowledge' rival to pictorialism, is not itself an alternative theory but rather an indication of the direction in which an adequate theory might be sought - that is, as a theory of high-level belief or knowledge representation.

Pylyshyn's central criticism of pictorial theories echoes Descartes (1637), who insisted that it is enough that the mind adequately *represent* the properties of the world and does not have to *share* them. In the same vein, S. Edelman (1998), recently says nobody thinks that a mental representation of a cat is furry. Perhaps not, but it is telling that such views must be repeatedly refuted throughout the history of speculation about the mind.

For some reason the case for spatial properties has seemed much more persuasive than the same point regarding furriness. In view of their compellingness, such mistakes evoke Kant's (1781) distinction between mere errors and certain deeper, inherent cognitive illusions. Thus, I disagree with Pylyshyn only regarding his optimism in hoping that, by repeating his powerful arguments loudly and slowly, he might succeed this time where he has failed before. Sufficient grounds for my skepticism is the fact that the Imagery Debate is perhaps the most remarkable modern duplication of controversies concerning the nature of 'ideas' which have persisted not just for thirty years but since the seventeenth century. In this recent re-enactment, Pylyshyn has played Arnauld (1683) against Kosslyn's Malebranche (1712) See Slezak (1992, 1995, 2002).

Of course, Pylyshyn is not vindicated merely because he was anticipated by Descartes and Arnauld. The striking historical parallels suggest that the fundamental problems at stake do not arise in any essential way from the data of modern experiments and computational theories. Indeed, just as we would expect in this case, we see a recurrence of the same perplexities not only throughout history, but also in more or less independent domains of cognitive science today.

What these doctrines have in common is the mistake of assuming that we apprehend our mental states rather than just *have* them. It is clear why such an implicit conception

leads to positing a representational format - sentences or pictures - which is paradigmatically the sort of thing requiring an external, intelligent observer - the notorious homunculus. Computer simulation of certain theories does not necessarily prove pictorialism innocent of this charge. As Rorty put it, there is no advance in replacing the little man in the head by a little machine in the head. As Pylyshyn argues, resort to neuroscience is no help either.

Despite the jaundiced views of "philosophical" arguments (as distinct from "strictly empirical science") expressed by some pictorialists, Pylyshyn's critique suggests there remain grounds for Wittgenstein's (1953) gibe "in psychology there are experimental methods and *conceptual confusion*".

On the Origins of Perceived Sameness in Shape

Linda B. Smith (smith4@indiana.edu)

Psychology and the Program in Cognitive Science, Indiana University,
1101 East 10th Street, Bloomington, IN 47405

Background

What defines sameness in shape? A precise definition has proved elusive despite considerable theoretical and empirical efforts across several disciplines. However, a theory of shape is crucial to explaining human object recognition. The theoretical problem is that real instances of real categories are rarely ever the exact same shape. For example, rocking chairs, stuffed chairs, and desk chairs are the "same shape" only under some highly abstract description of shape. The present paper reports developmental evidence suggesting that this abstract description of object shape is a product of early category learning. The experiments focus on the period between 18 and 24 months of age, a period in which children progress from producing few object names (less than 100) to producing many (on average more than 200).

Experiment 1

There were two types of test stimuli: 3 dimensional lifelike replicas and 3-dimensional shape caricatures of the same things as illustrated in Figure 1. There were also two dependent measures of object recognition: (1) Recognitory play -- a child would be credited with recognizing an object as a phone if the child pretended to dial a number and/or talk on the object and (2) Name comprehension -- a child was credited with recognition if the child could select the target from among distractors given the name of the object. The children were divided into two groups according to noun vocabularies --- those with less than 100 nouns in their vocabulary and those with more than 100 nouns. Both groups of children recognized the Lifelike objects -- both by the play measure and the name comprehension measure. However, only the children with larger vocabularies recognized the Shape Caricatures. The fact that young children with few names for common do not recognize shape caricatures despite their accuracy in recognizing richly detailed instances of the same category indicates that the abstract representation of shape is a developmental product. The fact young children who are only slightly more advanced in their category knowledge recognize these shape caricatures suggests that early category learning plays a role in forming the processes of shape recognition.

Experiment 2

One possibility is that children learn to recognize shape caricatures, category by category. Alternatively, the developmental changes may be more general, changing how

children perceive shape similarities for novel as well as known objects. This question was addressed in a second experiment. Children were introduced to a lifelike but (for young children) novel object, for example, an artichoke. The children were taught the object's name. On the critical test trial, three shape caricatures were presented to the child, one of which was a shape caricature of the originally named exemplar. The child was asked to indicate the named object, for example, "Where's the artichoke here?" If children must master the relevant shape properties category by category, then this task should be very hard because the caricatured artichoke only preserves some aspects of the original shape. If, however, children, are developing general perceptual skills that apply to novel shapes, then children who recognize the caricatures of familiar objects might also recognize the caricatures of novel ones. The results support this second possibility. Children with more than 100 object names in their productive vocabulary readily recognized the caricature of the newly learned noun. Children with fewer than 100 object names did not. These results strongly suggest that children are learning something general about the shape similarities relevant to object recognition and categorization.

Conclusion

The findings indicate that a complete theory of shape and object recognition will be a developmental theory. The relation of these results to contemporary theories of object recognition will be discussed.

The Origins, Development, and Nature of Argument Understanding

Nancy L Stein (n-stein@uchicago.edu)
Department of Psychology, University of Chicago
5848 S. University Avenue Chicago, IL 60637 USA

Elizabeth R. Albro
Department of Psychology, Wheaton College
Norton, MA USA

The early emergence and development of argumentation skill are the topics of this presentation. We argue that the mental schemas used to understand interactive arguments are influenced by the desire to maintain, dominate, or dissolve a relationship as much as they are by the desire to persuade and understand another person's position. Goals about personal relationships influence reasoning, thinking, and decision-making throughout arguments and negotiation. What appears to be illogical reasoning or irrational behavior is often quite rational and coherent, when the personal goals of the arguers are revealed. Personal goals also influence the outcomes of a negotiation and memory for what is said during the verbal interchange.

Data from three developmental studies will be presented to illustrate the relationship between personal-social goals and the content, organization, outcome and memory for an argument. We present different types of empirical evidence in support of our hypothesis, and we compare our early emergence hypothesis to the claim that argumentative skill emerges late in childhood and early adolescence. In support of our "early emergence" hypothesis, we focus on situations that are personally meaningful to young children and those that impact directly on their goals, beliefs, and well-being. We show that even the youngest children entering into an argument are able to generate and think about positive and negative reasons for pursuing different courses of action or for holding specific sets of beliefs.

We show, however, that argumentative thinking has an inherent bias that can be seen in adults' thinking as well as in young children's thinking. Arguers generally have more supporting knowledge for their own position than they do for their opponent's position. They also have more knowledge about the problematic aspects of their opponent's position than they do about their own position. Thus, they support a particular stance because they perceive more benefits accruing from their own position versus another.

We discuss the learning strategies that ameliorate this bias, both in social and in academic settings. We argue that current instructional strategies are often aimed at the wrong level of knowledge acquisition, in terms of teaching students how to write good arguments. The rhetorical concept of argument is often insensitive to the ways in which argument knowledge is stored psychologically. Most arguers, even adults, lack accurate knowledge about another's position. The focus for us, in terms of instruction and learning, has more to do with values, concerns, and beliefs underlying a position, the necessity to put each position on an equal

footing, and the willingness to consider the legitimacy of different goals.

Therefore, we discuss the cognitive and emotional effects of a mediated conflict resolution training procedure. Our mediated instruction focuses on explanations for holding positions, plans for generating new goals, and strategies for adding conditions to favored goals to make them acceptable to an opponent. The effect of participating in mediated training is an increased understanding and accuracy of the opponent's position. By increasing understanding for the other's position, the participant incorporates input from the other, thereby increasing the new words and concepts that occur in thinking and reasoning. The cognitive and language effects of mediation will be discussed and contrasted with the effects of self-imposed compromises and negotiations that do not entail compromise.

Constructive Perception: An Expertise to Use Diagrams for Dynamic Interactivity

Masaki Suwa (suwa@sccs.chukyo-u.ac.jp)

Information and Human Activity, PRESTO, JST &
School of Computer and Cognitive Sciences, Chukyo University
101 Tokodachi, Kaizu, Toyota, Aichi 470-0393 Japan

Diagrams Provide Dynamic Interactivity

By diagrams, we mean diagrammatic representations people use externally to their mind. They include pictures, sketches, charts, graphs and scribbles on napkins. Past literature (e.g. Anderson, Meyer and Olivier Eds, 2002) indicated that diagrams play facilitatory roles in inference and problem-solving; they reduce working memory load, serve as retrieval cues to evoke relevant information that might not otherwise be retrieved, promote inference by enabling perceptual judgements, and/or provide visuo-spatial cues for proper understanding of the structure of a problem. To serve these functions, the interpretation of the diagram needs to be static; it must stay the same in order not to introduce error in the operations performed from the diagram.

However, what diagrams could provide is not limited to such static interactivity. Rather, people using diagrams are encouraged to interpret them dynamically; the same appearance of parts of a diagram, especially when the diagram is vague and ambiguous, could evoke different interpretations at different times, dependent on what other elements surround the parts in focus at the moment or what the person has been thinking of. The situated cognition view (e.g. Clancey, 1997) corroborates this phenomenon. Dynamic interactivity of this sort afforded by diagrams is beneficial because it often enables dynamic construction of new thoughts on the fly in a situated manner.

A typical situation is design. Designers draw freehand sketches, often vague and ambiguous ones, and thereby see new features and relations among elements that they have drawn, ones not intended in the original sketch (Schon, 1983). These unintended discoveries promote the dynamic construction of new ideas and refine current ones. In recent years, we have explored ways that designers use sketches to dynamically construct design thoughts. Using the technique of protocol analysis, we examined the cognitive processes of experienced designers as they design through sketching. These protocols showed that the discovery of unintended perceptual features in sketches becomes a significant impetus for the generation of new ideas. Moreover, the generation of new ideas, in turn, was likely to become an impetus for further discovery of unintended perceptual features, so that each component process drives the other (Suwa, Gero and Purcell, 2000).

Constructive Perception to Benefit from Dynamic Interactivity

Dynamic interactivity, however, is by no means automatic when a diagram is available. To make it happen in using

diagrams requires some cognitive skill, i.e. what we call constructive perception. By constructive perception, we mean self-awareness of the ways that perception underlies interpretations of diagrams. The self-awareness allows searching for other ways to perceive, enabling reorganization of the diagram to promote novel interpretations. We have found that this skill is useful in two different domains (Suwa, Tversky, Gero and Purcell, 2001). One is the design domain. During a conceptual design process, an experienced architect was likely to make unintended discoveries when he reorganized perception using this skill voluntarily. The other is in the task of multiple interpretations of ambiguous drawings. Novices instructed about this skill generated more interpretations from a single ambiguous drawing, and exhibited slower rate of decline of generation of interpretations over time, than those not instructed. Moreover, we have found that experienced designers are superior to laypeople in this skill (Suwa and Tversky, 2001). These findings raise two issues, one cognitive and the other didactic. What constitutes the expertise of constructive perception? How can people be trained to use it? Research on these will promote successful use of diagrams in people's intellectual activities, e.g. in learning environments.

Literary text as a cognitive science problem

As a natural expansion from the tradition of natural language processing research, this paper presents our approach toward the poetic and artistic aspects of the human cognitive system. Our mental processes wouldn't stop when they understand the meaning of text. We always evaluate and appreciate them. Sometimes we contemplate, mediate and are moved. Cognitive science needs to invent vocabularies to describe these aspects of mental processes.

We assume that the interesting natures of literary texts are projecting following important problems:

- (a) Successful literary texts attract readers, give motivations to read through, evoke subjective emotional experiences of "moved". (emotion problem)
- (b) Many literary texts deal with fictitious contents. Transfer of factual knowledge may not be a major task of those texts. (knowledge problem)
- (c) Successful literary texts receive high evaluations as artistic artifacts. Society of intelligent agents has mechanism to support such social activities. (art problem)

Based on psychological evidences, we have proposed an emotion oriented natural language processing model, particularly, a *wish* generation mechanism and an *aesthetic emotion* evocation mechanism (Tokosumi, 2001, Yoshimine and Tokosumi, 2001). The present paper is an attempt to give a partial answer to the emotion problem, and suggests possible solutions for the knowledge problem and the art problem.

Cognitive Computation hierarchy

The concept of affective computing (Picard, 1997) has advanced the way we talk about cognitive activities. Literary computing as a subordinate of aesthetic computing may bring new perspectives into the way we talk about language processing (Fig. 1)

Knowledge Computing

knowledge representation, case-based inference, ...

Fig. 1. Cognitive computation hierarchy.

In the set of programs called KEWP (Knowledge and Emotion Workbench Programs), we have been formalizing people's emotional experiences evoked by stories and other multimedia objects, which include content oriented emotions and aesthetic emotions.

Aesthetic emotions in literary experiences

Aesthetic emotions evoked by the quality of objects, such as linguistic expressions and other artistic forms, are important class of emotions yet to be investigated fully. Our treatment of aesthetic emotions described here is based on the cognitive theories of emotion (e.g. Frijda, 1986). We identify a cognitive appraisal component and an action readiness component for various aesthetic experiences and propose computational mechanisms to implement those components in the KEWP model.

Cognitive factors each component can deal with are:

- (a) Cognitive appraisal component -- completeness, novelty, memory, ability recognition, competence, assimilation.
- (b) Action readiness component -- possession, re-experience, creation, evangetic.

We also discuss the implication of the model as a competence-based neural architecture of the brain (Tokosumi et al., in press).

Diagrams : A Cognitive Tool

Diagrams, such as maps, charts, graphs, and widely used as cognitive tools to promote memory and information processing, serving a variety of situated roles. They offload limited capacity working memory; they promote the use of space in inference and reasoning, they provide common ground for collaborative design (e. g., Kirsch, 1995; Larkin & Simon, 1987; Tversky, 2001).

One reason for the effectiveness of diagrams is that they map real or conceptual elements and relations to graphic elements and spatial relations in diagrammatic space. Diagrams have a rudimentary semantics and syntax. Diagrammatic elements, such as lines, blobs, crosses, and arrows have many possible interpretations derived from their geometric properties, but are disambiguated in context, much like the verbal concepts they approximate, such as relation and area. The elements can be combined in constrained ways to produce a multitude of meanings. This schematization has been a consequence of long term interactive situated use. Diagrams also use the spatial relations among elements to convey conceptual relations preserving varying levels of information, categorical, ordinal, interval.

Diagrams for Clarity

Diagrams can be used to organize and convey information and instructions, as in route maps and assembly directions. Here, the primary use is to instill prescribed information or linear actions. This will be exemplified by two projects on production and use of diagrams, one in route finding and the other in object assembly. In both cases, descriptions and depictions reveal the same underlying conceptual structure for traversing a route or assembling an object. These structures include both representations and procedures.

Diagrams for Creativity

Diagrams can also function to aid inference and promote creativity. Here, the goal is to come up with new ideas, ideas not anticipated by the designer of the diagram. This will be described by Suwa (2002; Suwa & Tversky, 2001) in a project on diagrams generated and used in design.

In both cases, diagrams are inevitably replete with ambiguity. In the former, context disambiguates, instilling clarity and avoiding confusion. In the latter, ambiguity is a resource for creativity.

Abstract

When attempting to solve a problem, individuals may activate multiple potential representations for that problem. Further, different representations may be activated more or less strongly. This study investigated how strength of problem representations is related to patterns of strategy use and strategy discovery. We hypothesized that the more strongly a particular representation is cued, the more likely participants should be to use a strategy that corresponds with that representation. Further, for individuals who do not initially have a corresponding strategy in their repertoires, the more strongly a particular representation is cued, the more likely participants should be to discover a strategy that corresponds with that representation. These hypotheses were investigated among adults solving word problems about constant change. The problems could be represented in terms of discrete change or continuous change. We varied two types of cues to discrete and continuous problem representations: linguistic cues and graphical cues. Both linguistic and graphical cues influenced strategy use, and the effects of the two cue types were additive. Among participants who did not use a continuous strategy at the outset of the study, discovery of a continuous strategy was relatively rare, and only participants who received a continuous graph tended to discover a continuous strategy. The findings suggest that it may be fruitful to consider problem representations as graded and variable rather than all-or-none.

Introduction

One step in the process of solving a problem is forming a mental representation of important features of that problem. Problem representations have been invoked to explain many aspects of people's problem-solving behavior, including success, solution times, strategies, and errors (e.g., Kotovsky, Hayes, & Simon, 1985; Lovett & Schunn, 1998). In the present study, we investigate links between problem representations and patterns of strategy use and strategy discovery.

Problem representations are sometimes conceptualized as integrated wholes, such that a particular representation is retrieved in its entirety from memory, and applied to the problem at hand (e.g., Larkin, 1983). Although this characterization may apply in some cases (e.g., for well-

practiced problems), we suggest that in most cases, problem representations are constructed at the moment of solving, based on both perceivable features of the problem and on knowledge retrieved from memory about problem content or about particular problem-solving strategies (McNeil & Alibali, 2000). We further suggest that the knowledge activated in constructing a problem representation may be more or less strongly activated, and thus, aspects of the representation may be graded rather than all-or-none (see Munakata, McClelland, Johnson, & Siegler, 1997, for discussion).

There is some support in the literature for the notion that problem representations may be graded. Kaplan and Simon (1990) studied this issue in the context of the *mutilated checkerboard* problem. In this problem, the squares from two diagonally opposite corners of a checkerboard are removed, and the solver's task is to cover the remainder of the checkerboard with dominoes, each of which covers exactly two squares, or to prove that such a covering is impossible. Because the two diagonally opposite corners of a checkerboard are the same color (both black or both white), the covering task is indeed impossible; however, this fact is notoriously difficult for solvers to discover. In their experiment, Kaplan and Simon varied the strength of various cues to the "paired-ness," or parity, of the squares. Solvers were quicker to discover that the covering was impossible when adjacent squares were labeled "bread" and "butter" than when the squares were not labeled, or when they were labeled with terms that did not form a strongly associated pair ("black" and "pink"). The bread-and-butter cue to parity facilitated a stronger representation of this crucial problem feature, and this led to faster discovery of the problem solution.

The purpose of the present study was to investigate whether variations in the strength of problem representations can account for variations across solvers in patterns of strategy use. Several past studies have investigated the links between problem representation and strategy use (e.g., Alibali, Bassok, Solomon, Syc, & Goldin-Meadow, 1999; Morales, Shute, & Pellegrino, 1985; Siegler, 1976). However, to date, little research has examined how the *strength* of representations relates to patterns of strategy use. We hypothesized that the more

strongly a particular representation is activated, the more likely participants would be to use a strategy that corresponds with that representation. Further, for individuals who do not initially have a corresponding strategy in their repertoires, the more strongly a particular representation is activated, the more likely participants would be to discover a strategy that corresponds with that representation.

We also wished to examine the effects on strategy use of having multiple, incompatible representations that are simultaneously active. We hypothesize that the operative factor in determining which representation guides solution is the *relative* strength of a particular problem representation. Therefore, when multiple, potentially incompatible problem representations are simultaneously active, participants' performance should be more variable than when a single problem representation is active.

This study investigated these hypotheses among adults solving word problems about constant change (Bassok & Olseth, 1995). The problems could be represented in terms of either discrete, stepwise change or smooth, continuous change. The experiment varied two types of cues to discrete and continuous problem representations: linguistic cues and graphical cues. The linguistic cues were drawn from previous research on people's verbal descriptions of constant change problems (Alibali et al., 1999). The graphical cues were chosen based on previous research about graph comprehension (Zacks & Tversky, 1999), which indicated that line graphs cue representations of continuous changes in values, whereas bar graphs cue representations of discrete changes in values.

In some conditions in the present experiment, the linguistic and graphical cues converged on a single representation. In other conditions, linguistic cues alone were provided. In still other conditions, the linguistic cue pointed toward one representation and the graphical cue pointed toward the other representation. If stronger representations lead to more frequent use of a corresponding strategy, participants should use that strategy most often in the corresponding cues case, and least often in the conflicting cues case. The single-cue case should fall somewhere in the middle.

Method

Participants

Participants were 158 Introductory Psychology students at the University of Wisconsin—Madison. The sample included 58 males, 90 females, and 10 participants who did not disclose their gender. Most participants were either freshmen (58%) or sophomores (23%), and all had taken at least one semester of college-level mathematics. Students received extra credit points for Introductory Psychology in exchange for their participation.

Procedure

Students were tested in a small classroom in groups of 15 to 25. They were given up to 45 minutes to complete a set of 10 story problems. They were instructed to work the

problems in the order presented and not to return to earlier problems after solving later ones. They were also asked to show all of their work and to circle their final solution for each problem. Students were not permitted to use calculators.

Materials

Students received a packet of 10 word problems about constant change, based on those used in prior studies (e.g., Alibali et al., 1999; Bassok & Olseth, 1995). The first 8 problems in each packet focused on quantities that changed continuously (e.g., rain falling, a tree growing), and these problems were the site of the manipulation. As seen in Table 1, the wording of the problems was varied to cue either a discrete representation or a continuous representation. Cues to the discrete representation included amount-like units for the initial and final quantities (e.g., 5 millimeters), mention of individual units of time (e.g., the 12 weeks), and explicit reference to the constant. Cues to the continuous representation included rate-like units for the initial and final quantities (e.g., 5 millimeters per week), mention of the entire period of time (e.g., the 12-week period), and explicit reference to rate.

In addition, as seen in Figure 1, the problems were accompanied either by bar graphs, by line graphs, or by no graphs at all. Thus, the study utilized a 2 (verbal cues: discrete or continuous) \times 3 (graphs: discrete [bar], continuous [line], or none) between-subjects design. The final two problems were transfer problems that were the same across all conditions, and they utilized discrete content (e.g., plants per row in a garden), discrete wording, and no graph. Participants' performance on the transfer problems is not addressed in this paper.

Table 1: Sample Problems

Discrete Wording

A sapling grows for 12 weeks. The number of millimeters it grows in each successive week increases by a constant from the number in the previous week. In the first week the sapling grows 5 millimeters and in the twelfth week it grows 137 millimeters. How many millimeters does the sapling grow in total over the 12 weeks?

Continuous Wording

A sapling grows for a period of 12 weeks. The rate at which it grows increases steadily over the period, from 5 millimeters per week at the beginning of the first week to 137 millimeters per week at the end of the twelfth week. How many millimeters does the sapling grow in total over the 12-week period?

Coding

Each problem was initially scored as correct, incorrect, or no response. Next, the strategy that each participant used to solve each problem was coded, and all strategies were

classified as either discrete, continuous, or other (unclassifiable). Coding definitions are presented in Table 2. Most strategies in the "other" category were conceptually flawed attempts to solve the problems (e.g., adding or multiplying the initial and final values, or multiplying the initial value by the number of intervals and then adding the final value).

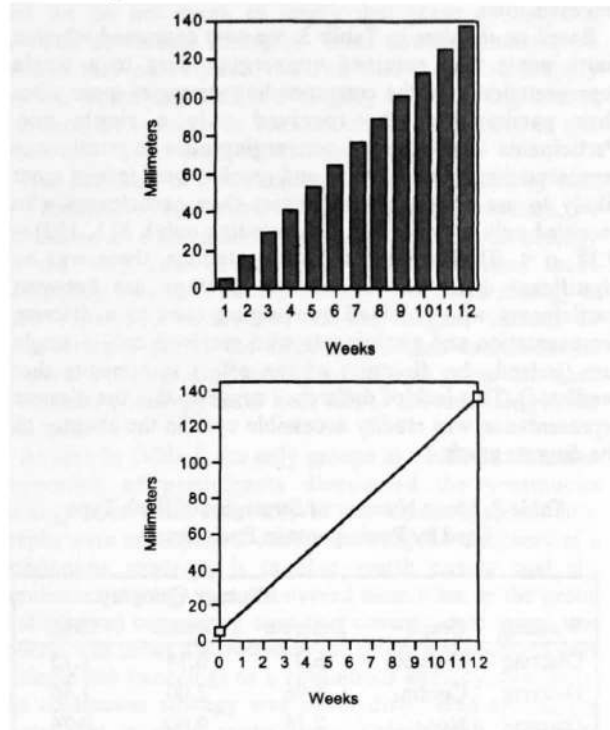

Figure 1: Sample bar and line graph.

Data from a subsample of 30 participants were rescored by a second coder to establish reliability. Agreement between the coders was 97% ($N = 282$ problems).

Table 2: Strategy Codes

Strategy	Definition
<i>Discrete Strategies</i>	
Sum	Participant finds the constant increase, calculates the value for each interval, and adds these values
Gauss	Participant adds values for initial and final intervals and multiplies this sum by half of the number of intervals
<i>Continuous Strategies</i>	
Average	Participant finds average value per interval and multiplies by number of intervals
Calculus	Participant sets up equation and integrates
Area	Participant calculates area using geometric methods (e.g., adds areas of rectangle and triangle)

Results

Our analysis focuses on the effects of cues to discrete and continuous representations on participants' overall level of performance, their strategy use, and their strategy discovery. The analyses reported here focus on the first eight problems, where the experimental manipulation occurred.

Problem solutions

We first examined whether variations in problem wording and graphs influenced whether participants solved the problems correctly. The interaction of wording and graphs was not significant, but there were main effects of both factors. As seen in Figure 2, participants who received problems with discrete wording were more successful than participants who received problems with continuous wording, $F(1, 152) = 7.22, p < .01$, despite the fact that all of the problems involved quantities that changed in a continuous fashion. Graphs also influenced success, $F(2, 152) = 3.61, p < .05$. Participants who received problems with continuous graphs performed most poorly, and participants who received discrete graphs and no graphs performed similarly well. Post hoc tests indicated that the discrete-graph and no-graph groups each differed significantly from the continuous-graph group, but they did not differ from one another.

Why were continuous wording and continuous graphs associated with poorer performance? Before addressing this question, we first consider patterns of strategy use.

Figure 2: Proportion of problems solved correctly by participants in each group.

Strategy use

Participants used discrete strategies much more often than continuous strategies in the dataset as a whole (63% vs. 16% of trials). Because of this, we used frequency of discrete strategy use rather than frequency of continuous strategy use as the dependent measure in our analysis of strategy use, to avoid possible floor effects in some of the cells of the design.

Once again, the interaction of wording and graphs was not significant, but there were main effects of both factors. As seen in Figure 3, participants who received discrete wording used discrete strategies more frequently than participants who received continuous wording, $F(1, 152) = 6.97, p < .01$. Graphs also influenced whether participants used discrete strategies, $F(1, 152) = 15.10, p < .001$. Participants who received continuous graphs used discrete strategies least often, and participants who received discrete graphs and no graphs used discrete strategies much more often. Post hoc tests indicated that the discrete-graph and no-graph groups both differed significantly from the continuous-graph group, but they did not differ from one another. Thus, both types of cues influenced participants' strategy use, and the effects of wording and graphs appear to be additive.

Figure 3: Number of problems solved using discrete strategies by participants in each group.

We now return to the question of why continuous wording and continuous graphs were associated with poorer problem-solving success in the initial analysis. The strategy analysis indicates that participants who received continuous wording or continuous graphs were less likely to use discrete strategies. Perhaps participants also applied discrete strategies more successfully than continuous ones, and this accounts for the performance differences seen in Figure 2. However, the success rates for discrete and continuous strategies did not differ. Participants succeeded on 50% of trials on which they used discrete strategies ($N = 1012$), and 52% of trials on which they used continuous strategies ($N = 238$).

To shed additional light on the performance differences, we examined the number of trials (out of 8) on which participants used discrete strategies, continuous strategies, or other, unclassifiable strategies, which were typically incorrect. These data are presented in Table 3. As seen in the table, participants who received continuous wording or continuous graphs used more strategies in the "Other" category than participants who received discrete wording

and discrete graphs, or discrete wording and no graphs. Strategies in this category were often conceptually flawed attempts to solve the problems, suggesting that participants who received continuous wording or graphs were often at a loss as to how to solve the problems. They may have attempted various strategies in an effort to generate or discover a strategy compatible with the continuous problem representation.

Based on the data in Table 3, we next examined whether participants who received converging cues to a single representation used the corresponding strategies more often than participants who received only a single cue. Participants who received converging cues to continuous representations (i.e., wording and graphs) were indeed more likely to use continuous strategies than participants who received only a single cue (i.e., wording only), $F(1, 152) = 9.38, p < .01$. For discrete representations, there was no significant difference in discrete strategy use between participants who received converging cues to a discrete representation and participants who received only a single cue (indeed, the direction of the effect is opposite that predicted). This lack of difference suggests that the discrete representation was readily accessible even in the absence of the discrete graph.

Table 3: Mean Number of Strategies of Each Type Used by Participants in Each Group

Wording	Graph	Strategy Category		
		Discrete	Contin.	Other
Discrete	Discrete	6.07	0.74	1.15
Discrete	Contin.	3.96	2.00	1.46
Discrete	None	7.16	0.00	0.76
Contin.	Discrete	5.59	0.59	1.78
Contin.	Contin.	2.15	3.11	2.70
Contin.	None	5.46	0.92	1.54

We also compared the strategy use of participants who received converging cues to a single representation and participants who received cues to both representations. Participants who received converging cues to discrete representations used discrete strategies more often than participants who received discrete wording and continuous graphs, $F(1, 152) = 5.46, p = .02$, but they did not differ significantly from participants who received continuous wording and discrete graphs. Participants who received converging cues to continuous representations used continuous strategies more often than participants who received continuous wording and discrete graphs, $F(1, 152) = 12.62, p < .001$, but they did not differ from participants who received discrete wording and continuous graphs, although the effect was in the predicted direction, $F(1, 152) = 2.18$. This pattern of findings suggests that, for problems like those used in the present study, graphs may be more effective than wording as a cue to problem representations.

Strategy discovery

We next turn to the issue of strategy discovery. As noted above, continuous strategies were used relatively infrequently in the dataset as a whole. However, some participants who did not use continuous strategies at the outset of the session appeared to "discover" continuous strategies in the course of solving the eight problems. Note that we do not mean to imply that these participants invented continuous strategies "from scratch." Instead, we believe that participants realized that they could apply familiar techniques such as averaging or calculating area as a method for solving the constant change problems. In this sense, they "discovered" continuous strategies.

Was discovery of a continuous strategy facilitated by cues to a continuous representation? To address this question, we eliminated all participants who used a continuous strategy on the very first problem ($N = 19$), because those participants may have already had the continuous strategy in their repertoire before the session began, instead of discovering it during the session. We then examined the proportion of remaining participants in each group who used a continuous strategy on at least one of the remaining seven problems.

As seen in Table 4, the only groups in which a substantial proportion of participants discovered the continuous strategy were those that received continuous graphs. Thus, graphs were an important cue in fostering the discovery of a continuous strategy. It is also worth noting that the continuous strategy was discovered most often in the group that received converging cues to a continuous strategy, and indeed, was never discovered in the group that received only a single cue (wording) to a continuous strategy. Similarly, the continuous strategy was never discovered among the group that received continuous wording with a discrete graph. However, 18% of participants who received discrete wording with a continuous graph discovered the continuous strategy. On the whole, the data are compatible with the view that a stronger representation is more likely to lead to strategy discovery.

Table 4: Percent of Participants in Each Group Who Discovered a Continuous Strategy

Wording	Graph	% who Discovered Continuous Strategy
Discrete	Discrete	8
Discrete	Contin.	18
Discrete	None	0
Contin.	Discrete	0
Contin.	Contin.	26
Contin.	None	0

Discussion

In this study, both linguistic and graphical cues to problem representations influenced participants' strategy choices and strategy discovery. The overall analysis indicated main effects of both cue types on success and strategy use.

Focused contrasts indicated that participants who received converging cues were more likely to use a target strategy than were participants who received a verbal cue to the target representation but a graphical cue to the alternative representation. For the continuous representation, participants who received converging cues were also more likely to use corresponding (continuous) strategies than participants who received the wording cue alone (i.e., with no accompanying graph). However, for the discrete representation, participants who received converging cues and participants who received wording cues alone used corresponding (discrete) strategies about equally often.

Although discovery of a continuous strategy was rare in the sample as a whole, graphical cues appeared to be especially important for strategy discovery. Continuous strategies were discovered most often in the group that received converging cues to a continuous representation, and second most often in the group that received discrete wording with a continuous graph. These findings underscore the importance of graphical representations in helping individuals construct mental models of problem situations. Our findings are compatible with Kalchman, Moss and Case's (2001) claim that line graphs are especially important in the development of understanding of mathematical functions.

Several aspects of the results converge to suggest that the "default" representation for constant change problems is one of discrete rather than continuous change. First, the large majority of problems were solved using discrete strategies. Second, participants who received bar graphs performed similarly to participants who received no graphs at all. This suggests that participants did not need the aid of the bar graphs in order to construct discrete mental models of the problem situations. They appeared to construct discrete representations spontaneously, even in the absence of the bar graphs. In contrast, participants who received line graphs performed quite differently from participants who received no graphs. The line graphs appeared to help participants construct continuous mental models of the problem situations, as the strategy discovery data suggest.

Why might discrete representations be more readily available to participants than continuous ones? One possibility has to do with the nature of the mathematical relations that are involved in working with the representations. Strategies compatible with discrete representations tend to rely on additive relations (e.g., summing the values for each increment), whereas strategies compatible with continuous representations tend to rely on multiplicative relations (e.g., multiplying the average value times the number of increments). Because additive relations are simpler and more fundamental than multiplicative ones, they may be noticed first. This hypothesis implies that individuals with strong mathematics skills should be especially likely to use continuous strategies a possibility we intend to examine in future work.

Even participants who received both linguistic and graphical cues to a continuous representation used continuous strategies relatively infrequently. The high incidence of unclassifiable strategies among participants who received continuous cues suggests that many

participants were unable to generate a strategy compatible with the continuous representation. It is possible that some of these unclassifiable strategies were generated based on hybrid representations that combined both discrete and continuous elements. If the "default" representation for constant change problems is discrete, as we argued above, then cues to a continuous representation may create a situation in which multiple, incompatible representations are simultaneously active. Indeed, many of the unclassifiable strategies included both additive components, reminiscent of discrete strategies, and multiplicative components, reminiscent of continuous strategies. A more detailed analysis of these unclassifiable strategies may shed light on processes of strategy construction.

It also seems worth noting that a small number of participants altered the presented graphs. On problems with line graphs, some participants drew lines down to the x-axis to "discretize" the graph, and on problems with bar graphs, some participants drew a line across the tops of the bars to "linearize" the graph. In this regard, it is interesting to note that participants who received discrete wording and a discrete graph were slightly more likely to use continuous strategies than participants who received discrete wording and no graph. It is possible that even a bar graph can sometimes cue a continuous representation, because the linear relationship between the variables is an emergent feature of the bar graph.

In sum, the present findings add to the body of literature elucidating the links between problem representation, strategy use, and strategy discovery. For constant change problems, graphical representations, and in particular, line graphs, were important cues to strategy use and strategy discovery. However, many participants in this study failed to discover a continuous strategy. The findings suggest that people often activate multiple representations for individual problems, and if these representations are incompatible, people may have difficulty generating an effective strategy for solving the problems. More generally, the present findings suggest that, to understand patterns of strategy change and strategy discovery, it is fruitful to conceptualize problem representations as graded and variable rather than all-or-none.

Acknowledgments

We thank Leslie Petasis for assistance with a pilot study that led up to this project, Maureen Kaschak for assistance with data collection and coding, and Nicole McNeil and the members of the Cognitive Development Research Group at the University of Wisconsin—Madison for helpful feedback and suggestions.

Abstract

An old but important debate about human memory concerns whether decay (indexed by time) or interference (indexed by amount of distracting information) is the cause of forgetting. We argue, based on a simple functional analysis, that this is a false dichotomy. Both processes must be at work, in that distracting information must decay to allow the cognitive system to have any hope of retrieving target information amidst the unavoidable clutter of a well-stocked memory. This analysis predicts that subtle decay effects should be pervasive, even in data produced by interference theorists to show that decay was impossible. A re-analysis of data from Waugh and Norman (1965) does indeed reveal decay effects that were dismissed by the authors as inconsequential and have been ignored by most investigators since. We fit a formal model integrating decay and interference to the Waugh and Norman data, and to the decay data of Peterson and Peterson (1959) to show that one model provides an improved account of two ostensibly divergent data sets.

Introduction

"Decay must be one of the most discredited theories in psychology, amongst many distinguished competitors."
— Memory researcher Robert Bjork, Michigan State University, Sept. 27, 2000.

How is information lost from human memory? Of the many potential metaphors, the two main competitors have historically been decay (a process indexed by time) and interference (a process indexed by the amount of distracting information "cluttering up" the mental desktop).

Of these two metaphors, decay has been the less popular, as the quotation above suggests. Memory researchers have often simply not wanted to credit the idea that memory could deteriorate by a time-indexed biological process (e.g., Keppel & Underwood, 1962; McGeoch & Irion, 1952; Postman, 1971; Waugh & Norman, 1965). Evidence often cited against decay includes the slowdown of forgetting during sleep (e.g., Ekstrand, 1972), though to interpret this slowdown as evidence against decay one must assume that the decay rate is the same during sleep as during wakefulness. Given the controversial nature of what little we do understand about brain activity during sleep, it seems equally likely that the decay rate is different in different states of consciousness. Another argument against decay is based on the observation that time by itself cannot be causal. As famously put by McGeoch, "In time, iron may rust and men grow old, but the rusting and the aging are understood in terms of the chemical and other events which occur in time, not in terms of time itself" (McGeoch & Irion, 1952, p. 402). Today, many important memory theories exclude

decay (e.g., Gillund & Shiffrin, 1984; Hintzman, 1988; Murdock, 1992), and cognitive textbooks often present decay theory as a historical footnote rather than as an active hypothesis (e.g., Ashcraft, 2002; Galotti, 1999; Reed, 2000.)

But decay is far from a footnote. Since the original studies of Brown (1958) and Peterson and Peterson (1959), various approaches have been taken to try to isolate decay from interference (Reitman, 1974; Baddeley & Scott, 1971; Turvey, Brick, & Osborne, 1970). Interference theorists themselves discovered that retention interval moderates proactive interference (e.g., Loess & Waugh, 1967). Decay is represented in select memory theories (Anderson & Lebiere, 1998; Richman, Staszewski, & Simon, 1995) and interpretations of the literature (Anderson, 2000; Baddeley, 1990; Wickelgren, 1977). Finally, it is increasingly clear that McGeoch's polemic (quoted above) misses the mark, given converging evidence that decay has neural correlates. For example, Fuster (1995, p. 247) observes that firing rates of particular pyramidal cells in the monkey show decay "reminiscent of the well-known decay of human short-term memory." And decay in the form of "leak currents" is an integral part of neural network simulation of the hippocampus (O'Reilly & Munakata, 2000).

The current study aims to bolster the case for a general and functional decay process and, more specifically, to show that evidence for decay exists behind "enemy lines," in the very data that purportedly showed that decay was impossible. The paper is organized as follows. We begin with a functional analysis that argues that decay (or some similar, non-interference forgetting process) must function in memory if memory is to function at all. We then develop predictions of this analysis for a classic study in the literature on interference, the Waugh and Norman (1965) probe digit experiment. A re-analysis of the data from that experiment supports the prediction of subtle decay effects. To make the prediction quantitative, we fit the data with a model based on a memory theory that offers the building blocks to integrate decay and interference. Finally, we turn to the original Peterson and Peterson (1959) data set on decay, and fit the same model to it. The goal is to show that one model, with decay and interference represented as functionally interacting processes, parsimoniously accounts for two ostensibly divergent data sets.

A Functional Perspective on Decay

The functional argument for decay is perhaps best illustrated with an example. As one drives an automobile through various speed zones, it is important to mentally register each change in the speed limit and update memory accordingly. However, if each change in the speed limit contributed

Figure 1. Left: Data from Waugh and Norman (1965), Exp. 1. Error bars are within-participants confidence intervals (Loftus & Masson, 1994) for the serial position \times presentation rate interaction. Right: Fit of the functional decay model.

monotonically to interference in memory for speed limits, it would quickly become impossible to remember the current speed limit, whatever it might be. Although interference is clearly a potent source of forgetting, even at long delays (Keppel, Postman, & Zavortink, 1968), there must be some mitigating process if memory is to support our everyday needs (c.f., Luria, 1968).

Interference theorists themselves have been forced to acknowledge this functional need, and the literature consequently has known decay by other names. One example of decay being reinvented is the notion of forgetting through “stimulus fluctuation” (Estes, 1955; Gillund & Shiffrin, 1984; Landauer, 1975). The hypothesis is that changes in the environment gradually reduce the set of cues available to activate distracting information. However, this gradual environmental change in how distractors are cued is typically only specified at an abstract level, in terms that are functionally equivalent to a simple time-indexed process. A second example is the mystical sounding “spontaneous recovery” of previously extinguished distractors. Inherited from the behaviorists, this construct was applied by early interference theorists to explain, among other findings, the effect of retention interval in the Brown-Peterson paradigm (Keppel & Underwood, 1962).¹ Again, however, spontaneous recovery and decay seem functionally equivalent: In one case distractors gain strength relative to the target, and in the other case the target loses strength relative to distractors.

Thus, we argue that any non-interference forgetting indexed by time may as well be known as decay. What we propose to do is play out the functional implications and search for decay in time-based experimental manipulations where one might not otherwise expect to find it.

Revisiting Waugh and Norman (1965)

The classic data set of Waugh and Norman (1965) is discussed in many modern cognitive textbooks (including those cited above) usually to illustrate the importance of interference as a forgetting mechanism. In the *probe-digit* paradigm used in this experiment, the participant is presented with a list of digits and then asked to report one of

them. The target digit (the one to report) is indicated by a probe digit given immediately after the list is presented. The probe also occurred exactly once during the list proper, and the target is the digit that followed the probe in the list proper. The serial position of the probe in the list proper changes randomly across trials, so accuracy across trials measures item retention as a function of serial position.

The experiment included a within-subjects manipulation of presentation rate to test whether the chronological age of the target item affected its retention. In the Fast condition, digits were presented once every 250 msec, and in the Slow condition they were presented once per second. The logic was that if decay caused forgetting, then Fast items should be more accurately remembered in response to the probe. If interference caused forgetting, then only serial position should affect retention. That is, late items in the list should be recalled better than earlier items, in both the Fast and Slow conditions, because late items suffered fewer intervening items before the probe, and hence should suffer less retroactive interference.

The Waugh and Norman data are plotted in Figure 1 (left panel), with serial position of the target along the x-axis. The curves represent the two presentation rates. The effect of serial position is readily apparent in both conditions, with later items recalled much more accurately than earlier items. This effect, and its similarity across the two conditions, was enough for Waugh and Norman to reject decay as cause of forgetting. They do note “a slight interaction” of serial position and presentation rate, but dismiss its importance — “the effect of rate is relatively small compared to the effect of serial position” — and report no statistics. Following their lead, no contemporary textbook that we have examined (including those cited above) even acknowledges the interaction, despite the fact that it fairly leaps off the page. The occasional investigator has observed the interaction and speculated about causes (Massaro, 1970; Hintzman, 1978; Wickelgren, 1977), but the theoretical significance of this interaction for decay theory has not been fully pressed.

To confirm the interaction statistically, we conducted a 9×2 repeated measures analysis of variance on the data.² The interaction of serial position and presentation rate is highly reliable, $F(8, 24) = 5.1, p < 0.001, MSE = .0033$.

¹“The increase in [proactive interference] with increase in length of the retention interval may be accounted for by the recovering of extinguished interference associations” (Keppel & Underwood, 1962).

² We reconstructed the Waugh and Norman data by digitally scanning the individual participant data graphs in that report and overlaying a grid to estimate the actual numbers.

The Functional Decay Model

To explain the Waugh and Norman interaction, we modeled it using the central memory constructs of the ACT-R cognitive theory (Anderson & Lebiere, 1998). The model's fit is presented in the right panel of Figure 1. In addition to qualitatively capturing the interaction, quantitative measures of fit are quite close, with $RMSD = .054$ and $R^2 = .965$.

This *functional decay* model is based on the activation mechanism illustrated in Figure 2. The two curves in that figure plot the activation of each item in a list, just before the probe is presented. That is, the curves represent a snapshot of every potential target's activation immediately after all the potential targets have been presented. The curves are produced by the following activation function, adapted from ACT-R's Base Level Learning equation.

$$A = \ln\left(\frac{n}{\sqrt{T}}\right) \quad \text{Equation 1: Base-level activation}$$

A is the activation of an item, n is the number of times the item has been retrieved from memory since it was encoded, and T is the age of the item (time from encoding to present). Equation 1 thus computes activation as a function of frequency of use. The premise behind this function is that historical need for information is a predictor of future need and thus should affect item availability (Anderson & Milson, 1989). Activation decays in this function as a power function of age of the item, T . The exponent of this function (-0.5) is, within ACT-R, a relatively constant parameter of the cognitive architecture governing the decay rate of a memory trace. However, this is not the only factor governing an item's base-level activation. For example, a rehearsal process could increase activation by increasing the value of the usage parameter, n . In the Waugh and Norman model, we fix n at 1, on the assumption that items were not differentially rehearsed. Waugh and Norman anticipated the possibility that differential rehearsal could confound their results, and instructed their participants to rehearse only the most recent item of the list, if they rehearsed at all.

In terms of the activation curves in Figure 2, Equation 1 (with n constant across items) predicts that the latest (most recent) item is the most active, the next most recent item the next most active, and so on. Items in the Slow condition are on average less active than items in the Fast condition, because a Slow item at a given serial position is older than a Fast item at the same serial position, so has decayed more.

In addition to the base-level activation governed by Equation 1, the second source of activation for a memory trace under ACT-R theory is priming through associative links. In other words, an item is activated associatively when cues to that item are themselves activated. Associative priming is how ACT-R must explain that fact that elements other than the latest (in the probe digit paradigm) can be retrieved at all. The background theoretical assumption is that, in response to a retrieval request from central cognition, the memory system delivers the trace that is the most active at that instant. In Figure 2, the item with the highest base-level activation is the last one in the list, so if base-level activation were the only activation a memory trace could have, then only the last item would ever be retrieved. This is clearly not how the cognitive system

operates, in the probe digit paradigm or in general; people are perfectly able to retrieve thoughts other than the most recent. ACT-R implies that such retrieval depends heavily on retrieval cues delivering activation through associative links. In Bayesian terms, base-level activation reflects the influence of history (retrieval history, in particular, as captured by base-level activation), whereas associative priming from retrieval cues reflects the influence of the current context.

In the probe-digit paradigm, we assume that the role of associative priming plays out through an associative link between the probe and the target. That is, when the probe and the target co-occur in the list proper, this co-occurrence causes an associative link to be encoded between the two traces in memory. When the probe is re-activated at the end of the list, activation spreads from the probe to the target through this link, priming the target. This assumption is grounded in associationism generally and various memory theories in particular (e.g., Gillund & Shiffrin, 1984), and in specific evidence that such associations are formed between neighbors in a list of random items (Nairne, 1983).

In the functional decay model, associative priming from the probe is implemented simply as a constant amount of activation added to the target. The effect of this priming is also illustrated in Figure 2, by the arrow labeled *priming*. Whereas the curves represent item activations immediately before the probe is presented, the elevated point at the head of the arrow represents the activation of a target when the probe is presented. (We have arbitrarily chosen the target to be the item at serial position 7, in the Fast condition.) The target item is shown to have much more activation than its neighbors, and also more activation than most recent list items (which would otherwise be the most active).

One other necessary model parameter, not represented in Figure 2, captures the differential effect (across the two presentation rates) of proactive interference due to previous trials. According to Equation 1, old items decay but

Figure 2: A snapshot of item activations from Equation (1) at the instant the full list of items has been presented. The arrow labeled *priming* indicates the magnitude of associative activation passing from probe to target (item 7, in this scenario) when the probe is presented. A and B are activation differences used to illustrate relative activation (see text).

nonetheless retain some activation well into the future, meaning that items from previous trials ("prior items") will continue to exist in memory as a source of proactive interference. However, the age of these prior items will differ across the Fast and Slow conditions, in that prior items in the Fast condition will retain more of their activation and hence cause greater proactive interference. This difference across the two conditions is captured in a prior-items parameter in the model. The parameter is implemented in terms of a single distracting element with an activation value that is estimated from the data.

The final step is to map item activations to the probability of retrieving a given target item. In ACT-R this mapping is the "soft-max" rule below, which predicts that the most active item has the highest probability of being retrieved (as we discussed above), but that other items can intrude from time to time. This rule determines the probability of retrieving a given item as a function of its activation relative to the activation of its distractors, and thus specifies the extent to which distractors interfere with the target.³

$$P_i = \frac{e^{A_i/s}}{\sum e^{A_j/s}} \quad \text{Equation 2: Retrieval probability}$$

P_i is the probability of retrieving i , the target, and A_i is the target's activation (from Equation 1). The quantity s represents the assumption that memory is susceptible to noise (i.e., transient fluctuations in activation levels).

Fitting Waugh and Norman (1965)

We can now describe how the model captures the interaction in Figure 1. One of the two basic patterns in the data is that late items are recalled better in the Slow condition than in the Fast condition. In the model, this effect results from late items having more *relative* activation in the Slow condition than in the Fast condition, as compared with distracting elements. By relative activation, we mean the difference in activation between the target and its distractors. Equation 2, which defines activation-based interference in ACT-R, predicts that the greater the difference in activation between the target and its distractors, the greater the probability of retrieving the target. In Figure 2, relative activation is represented by the differences A and B, which are differences in activation levels of items at two arbitrarily chosen serial positions (10 and 15). The difference A is between items 10 and 15 in the Fast condition, and the difference B is between items 10 and 15 in the Slow condition. When the target is a late item (i.e., 15), then the probability of retrieving it depends on the activation difference between it and earlier items (i.e., 10). This difference is larger in the Slow condition (distance B)

than in the Fast condition (distance A). Thus, late items will be recalled more accurately in the Slow condition than in the Fast condition.

The second pattern in the data is that earlier items are recalled better in the Fast condition than in the Slow condition. In the model, this effect again results from relative activation, with target and distractor now reversing roles. With respect to the scenario in Figure 2, when the target is the earlier item (i.e., 10), then the distractor is the late item (i.e., 15). (Recall that although item 10 has less base-level activation than item 15, the associative priming illustrated in Figure 2 will compensate for this deficit and improve the probability of the target being retrieved.) The activation difference between target and distractor now favors the Fast condition, because item 10 in that condition faces a smaller activation deficit relative to its primary distractors (the later items in the list). Thus, earlier items will be recalled more accurately in the Fast condition than in the Slow condition.

Model parameters

The fit in Figure 1 depends on estimating three parameter values from 18 data points. Activation noise (s in Equation 2), was estimated at 0.19, a value in line with other applications of this equation (e.g., Anderson, Bothell, Lebiere, & Matessa, 1998). The priming (associative activation) contributed by the probe digit was estimated at .83 units of activation. Finally, the prior-item activation (more specifically, the difference in prior item activation across the Fast and Slow conditions) was estimated at 1.1 units of activation. An Excel spreadsheet implementing the model and the two fits presented in this paper is at <http://www.msu.edu/~ema/functionaldecay>.

Fitting Peterson and Peterson (1959)

So far we have searched for and found evidence for decay in data on interference. Given our aim to integrate decay and interference functionally, we now turn to data on decay (Peterson & Peterson, 1959), and ask what role interference might play. The Brown-Peterson paradigm involves presenting a verbal item (e.g., a consonant trigram) and testing retention as a function of time. During the retention interval, verbal rehearsal is suppressed by a task like counting backwards. Figure 3 shows the data on recall accuracy from Peterson and Peterson (1959), Experiment 1. The x-axis shows retention interval and the y-axis shows proportion correct. The data show an even, negatively accelerating decline in accuracy with retention interval. This decline was interpreted to mean that maintenance of information in STM depended on active rehearsal, such that preventing rehearsal caused loss of information (Peterson & Peterson, 1959). Formal models of these data are not new (e.g., Baddeley, 1976, p. 130), but what is a novel integration is to explain these data on decay with the same processes that account for data on interference.

Our interpretation of the data in Figure 3 is that the current item (trigram) is represented in memory against a background of interfering items from previous trials. This kind of proactive interference has been demonstrated in a number Brown-Peterson studies (e.g., Dillon & Reid, 1969;

³ Equation 2, termed the Chunk Choice Equation in Anderson and Lebiere (1998), plays a broader role in defining interference in our model than in ACT-R proper. In ACT-R, retrieval probability is a function both of Equation 2 and of a threshold parameter τ that specifies a minimum activation below which an item is invisible to the system. We assume no such threshold; the probability of retrieving an item is solely a function of that item's activation relative to the activation of distractors. We thus place greater emphasis on the role of interference from distracting information.

Keppel & Underwood, 1962; Wickens, Born, & Allen, 1963). In our model, this proactive interference plays the same role here as prior-item interference did in fitting the Waugh and Norman data. An element of this mental clutter can intrude when the system attempts to retrieve the target — and is more likely to, the more the target has decayed. Thus, relative activation is again the factor determining retrieval accuracy. Here, however, relative activation is a factor between trials only, whereas in the probe-digit model it was a factor between and within trials. The only other change to the model was to remove associative priming as a source of activation for the target, reflecting the absence of a specific probe in the Brown-Peterson paradigm.

As shown in Figure 3, the model again fits closely, with $RMSD = .027$ and $R^2 = .977$. Fitting the model required estimating two parameters from six data points. Activation noise s (Equation 2) was estimated to be .34, which is again in the range used in other ACT-R models (Anderson et al., 1998). Prior item activation was estimated at -2.31 units.

Note that in fitting the Peterson and Peterson data we carried over the decay rate from the Waugh and Norman model (-.5). This illustrates the value of incorporating interference in a model of decay. A simple power-law decay model, without interference as a factor, is $P_i = a + bT_i^d$, with P_i the probability of retrieving item i , T_i the age of i , d the decay rate, and a and b free parameters. Fitting this model to the Peterson and Peterson data produces measures of fit $RMSD = .029$ and $R^2 = .973$, and parameter values $a = -19.8$, $b = 20.7$, and $d = -.14$. Of particular interest is the decay rate, -.14. This deviates substantially from the value of -.5 that we carried over from the Waugh and Norman model, and from many ACT-R models before that (Anderson & Lebiere, 1998). Thus, although the *apparent* decay rate may differ from situation to situation, we propose that what varies is not the *architectural* decay rate but the background level of interference, which is situation-dependent and thus a more plausible source of variation. Importantly, this variable can also be estimated quantitatively, for example by counting the number of trials preceding the trial of interest (Keppel & Underwood, 1962).

In sum, if interference is indeed a primary mechanism of forgetting, then it would be odd if it played no role in forgetting in the Brown-Peterson paradigm. Our analysis suggests that decay by itself cannot cause forgetting — forgetting arises because decay takes place *relative* to background interference in memory.

Discussion

We propose that decay and interference are functionally related processes — decay of distractors mitigates the extent to which they interfere with the target. Playing out the consequences of this proposal makes functional sense of an empirical result that has lain largely dormant for a generation, absent the right theoretical framework in which to interpret it. We have also formalized the integration of decay and interference in another sense, by fitting the Waugh and Norman data set and its “opposite,” the Peterson and Peterson data, with the same model. These model-fitting successes converge with our functional logic to argue that decay and interference must both operate in memory.

Figure 3: Data from Peterson and Peterson (1959), Experiment 1, and the fit of the functional decay model.

We began by hinting that if decay is important to the functionality of memory, then its effects should be found pervasively in behavioral data. Indeed, functional decay models similar to the one presented here have been applied to diverse domains. These include task switching (Altmann & Gray, 2002) and the time course of Stoop interference (Altmann & Davidson, 2001). Thus, the claim that decay is pervasive has some backing beyond our excursion here to the headwaters of the debate over forgetting mechanisms.

There are a number of caveats on the current work that will be important to address in the future. First, the Waugh and Norman interaction, though it seems visible in other probe digit data (Norman, 1966), needs to be replicated before we invest more in interpreting it. Second, our spreadsheet model needs to be implemented as a running simulation, to test whether we have missed important interactions among processes. Third, the model makes specific predictions about which distractor items should intrude in what proportions; later items should intrude more often, because they are more active. These predictions clearly need to be tested.

We should also note that the construct of relative activation underlying our model has other expressions in memory theory, such as the discrimination ratio (Baddeley & Hitch, 1993) and temporal distinctiveness (Neath, 1993). We would argue, however, that the grounding of the current model in ACT-R anchors it more directly to observable environmental processes. ACT-R is premised on the notion that memory is a mirror reflecting patterns of information need imposed by the environment. Thus, for example, retrieval frequency is a predictor of activation because it is also a predictor of impending need for that item. Consistent with the functional interpretation of decay, we favor a functional interpretation of memory generally, in which quantities like activation reflect the tasks that the memory system accomplishes for us.

Finally, we should emphasize that our claims about the importance of decay are not meant to conflict with the idea that interference is the dominant cause of loss of retrievable information in memory. Wherever they have been isolated, including in the Waugh and Norman data, the effects of decay are quite small (c.f., Reitman, 1974) compared to the effects of interference. Indeed, a small effect of decay is all that is functionally necessary to tilt retrieval probability toward the target, particularly when strategic memory processes like rehearsal are available for the system to manipulate target activation.

Abstract

Everyone agrees that real cognition requires much more than static pattern recognition. In particular, it requires the ability to learn *sequences* of patterns (or actions). But learning sequences really means being able to learn *multiple* sequences, one after the other, without the most recently learned ones erasing the previously learned ones. But if catastrophic interference is a problem for the sequential learning of individual patterns, the problem is amplified many times over when multiple *sequences* of patterns have to be learned consecutively, because each new sequence consists of many linked patterns. In this paper we will present a connectionist architecture that would seem to solve the problem of multiple sequence learning using pseudopatterns.

Introduction

Building a robot that could unfailingly recognize and respond to hundreds of objects in the world – apples, mice, telephones and paper napkins, among them – would unquestionably constitute a major artificial intelligence *tour de force*. But everyone agrees that real cognition requires much more than static pattern recognition. In particular, it requires the ability to learn *sequences* of patterns (or actions). This was the primary reason for the development of the simple recurrent network (SRN, Elman, 1990) and the many variants of this architecture.

But learning sequences means more than being able to learn a single, isolated sequence of patterns: it means being able to learn *multiple sequences*, one after the other, without the most recently learned ones erasing the previously learned ones. But if catastrophic interference – the phenomenon whereby new learning completely erases old learning – is a problem with static pattern learning (McCloskey & Cohen, 1989; Ratcliff, 1990), the problem is amplified many times over when multiple sequences of patterns have to be learned consecutively, because each sequence consists of many new linked patterns. What hope is there for a previously learned sequence of patterns to survive after the network has learned a new sequence consisting of many individual patterns?

In this paper, we will present a connectionist architecture that solves the problem of multiple sequence learning.

Catastrophic interference

The problem of catastrophic interference (or forgetting) has been with the connectionist community for well over a decade now (McCloskey & Cohen, 1989; Ratcliff, 1990; for a review see Sharkey & Sharkey, 1995). Catastrophic forgetting occurs when newly learned information suddenly and completely erases information that was previously learned by the network, a phenomenon that is not only implausible cognitively, but disastrous for most practical applications. The problem has been studied by numerous authors over the past decade (see French, 1999 for a review). The problem is that the very property – a single set of weights to encode information – that gives connectionist networks their remarkable abilities of generalization and graceful degradation in the presence of incomplete information are also the root cause of catastrophic interference (see, for example, French, 1992).

Various authors (Ans & Rousset, 1997, 2000; French, 1997; Robins, 1995) have developed systems that rehearse on *pseudo-episodes* (or pseudopatterns), rather than on the real items that were previously learned. The basic principle of this mechanism is when learning new external patterns to interleave them with *internally-generated* pseudopatterns. These latter patterns, self-generated by the network from *random* activation, reflect (but are not identical to) the previously learned information. It has now been established that this pseudopattern rehearsal method effectively eliminates catastrophic forgetting.

A serious problem remains, however, and that is this: cognition involves more than being able to sequentially learn a series of "static" (non-temporal) patterns without interference. It is of equal importance to be able to serially learn many of *temporal sequences of patterns*. We will propose an pseudopattern-based architecture that can effectively learn multiple temporal patterns consecutively.

The key insight of this paper is this:

Once an SRN has learned a particular sequence, each pseudopattern generated by that network reflects the entire sequence (or set of sequences) that has been learned.

From which our key result follows:

When learning a new sequence, simple rehearsal with these sequence-encoding pseudopatterns will prevent catastrophic forgetting of the previously learned sequence(s).

We will use a connectionist architecture using two coupled "auto-associative recurrent networks (AARN)" (Maskara & Noetzel, 1992, 1993; Cleeremans & Destrebecqz, 1997) that pass information back and forth to each other by means of pseudopatterns. We will refer to auto-associative recurrent networks as Reverberating SRNs (RSRN), in order to emphasize the manner in which they use pseudopatterns to eliminate catastrophic interference in multiple sequence learning.

The remainder of this paper is organized as follows. We will briefly review the standard dual-network pseudopattern solution to the problem of catastrophic forgetting in static pattern learning. We will then show (Simulation 1) that multiple-sequence learning is particularly susceptible to catastrophic forgetting. We will then show how our pseudopatterns-based dual-network architecture can be used to effectively overcome catastrophic interference in multiple sequence learning.

Overcoming catastrophic interference with pseudopatterns

Before discussing catastrophic interference in multiple-sequence learning, we need to briefly describe what pseudopatterns are and how they can be used to reduce catastrophic interference in the simpler case of static pattern learning.

Assume we have a three-layer feedforward network that learns a number of binary patterns drawn from some distribution. Assume, thereafter, that these patterns are no longer available. How can one determine, even approximately, what the network has learned? Answer: By "bombarding" the input of the network with *random* binary vectors and collecting the associated output vectors. Each input-output pair of vectors produced in this way will constitute a *pseudopattern* that will be a reflection of the function previously learned by the network.

The basic idea to use pseudopatterns to reduce catastrophic interference is due to Robins (1995). It works as follows. The network learns a first set of patterns, $\{P_i\}$. Then before it begins to learn a second set of patterns, $\{Q_i\}$, noise is fed through the network to produce a set of pseudopatterns, $\{\psi_i\}$, as above. These pseudopatterns are added to the new patterns to be learned and the network trains on this larger set until all of the new patterns, $\{Q_i\}$, are learned to criterion. When the network is tested on the originally learned patterns, $\{P_i\}$, it has not forgotten them catastrophically. Had there been no pseudopatterns mixed in with the new patterns that were learned, the network would have completely forgotten the originally learned patterns.

Dual-Network Architectures

But where are these internally generated pseudopatterns stored so that they can be interleaved with the new patterns? One answer is to generate them on the fly in a separate network (French, 1997; Ans & Rousset, 1997, 2000). Let us consider one way that a single new pattern, Q , might be learned in this dual-network model. Assume that new patterns are learned by NET 1 (this can be considered to be the "Performance Network"), while previously learned patterns are stored in NET 2 (which could be considered to be the "Storage Network"). NET 1 learns Q as follows:

- i) pattern Q is input to NET 1, which modifies its weights once;
- ii) noise is input to NET 2, which generates a pseudopattern;
- iii) this pseudopattern is presented to NET 1, which modifies its weights once;
- iv) if Q has been learned to criterion, stop; otherwise go to i).

We call this the "awake state". Once the output error for pattern Q has dropped below criterion, we transfer the information in NET 1 to NET 2 as follows:

- Loop N times: i) noise is input to NET 1, which generates a pseudopattern;
- ii) this pseudopattern is input to NET 2, which modifies its weights once.

We call this phase, when information is transferred to NET 2, the "sleep state." This will be the basis of all learning in the dual-network framework described in this paper.

"Reverberating" backpropagation

A reverberating backpropagation (RBP) network is a standard three-layer network that has a built-in autoassociator ("reverberator") for the input of the patterns to be learned (Ans & Rousset, 1997, 2000). We have shown this network in an "unfolded" manner (Figure 1). In this visualization, the output layer is divided into the "autoassociative" nodes for the input component of the patterns to be learned (on the left in Figure 1) and the "target" nodes for the targets of the patterns to be learned (on the right in Figure 1).

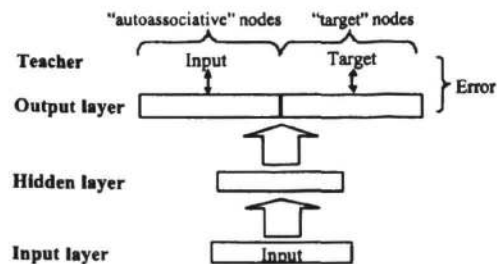

Figure 1. An RBP network

Assume the network is to learn a pattern $P: I \rightarrow T$, consisting of an input, I , and a target, T . I is presented on input and is sent through the network to the output layer. For all of the nodes in the output layer, an error is calculated. For the "autoassociative" output nodes,

the error is based on the difference between the network output and the original input, I , whereas for the "target" nodes, this error is based on the difference between the "heteroassociative" output and the desired target T . The errors associated with both the autoassociator and the target output nodes are then backpropagated through the network in order to change the network's weights.

"Attractor" pseudopatterns in an RBP Network

To generate pseudopatterns in a reverberating network, a random input i_ψ is presented to the input layer of the network and fed through to the output layer. The activation values of the "autoassociative" nodes in the output layer (nodes on the left of the output layer in Fig. 1) constitute a new input, i'_ψ , which is then sent through the network (the activation values on the "target" nodes in the output layer are ignored). This produces a pattern of activation on the autoassociative output nodes, i''_ψ , which is then presented to the input nodes of the network, and so on. After a number of reverberating cycles through the network, a final "reverberated" input, i_ψ^R , is sent through the network and the activation vector of all the output nodes (the "autoassociative" and the "target" output nodes), o_ψ , is used to produce a pseudopattern $\psi: i_\psi^R \rightarrow o_\psi$. The significant advantages of using an input autoassociator with a feedforward backpropagation network have been shown elsewhere (Ans & Rousset, 1997, 2000). Suffice it to say that the reverberation process transforms a pure random input, i_ψ , into an attractor of the system, i_ψ^R . An "attractor" pseudopattern produced provides a much better reflection of the old patterns than a pseudopattern produced from simple random noise on input. It is this reverberation technique that is largely responsible for the power of this technique.

Reverberating Simple Recurrent Networks (RSRN)

We will assume that the reader is familiar with the design of a Simple Recurrent Network (SRN, Elman, 1990). An RSRN (Figure 2) works very much like a standard SRN (Maskara & Noetzel, 1992, 1993; Cleeremans & Destrebecqz, 1997). Just as the RBP network involves adding "autoassociative" nodes to the output layer of a BP network, a reverberating SRN involves adding "autoassociative" nodes to the output layer of an SRN. The full input to the network consists of the "standard" input, i.e., the input from the sequence item, $S(t)$, and the "context" input, $H(t-1)$, which is the activation vector of the hidden

layer associated with the previous item in the sequence, $S(t-1)$.

"Attractor" pseudopatterns in an RSRN

The principle is identical to pseudopattern generation in an RBP network. Crucially, once the RSRN has learned a sequence of items, each "reverberated" pseudopattern generated by it reflects the entire sequence learned by the recurrent network. Each pseudopattern can be thought of as a very compact representation of the entire previously learned sequence.

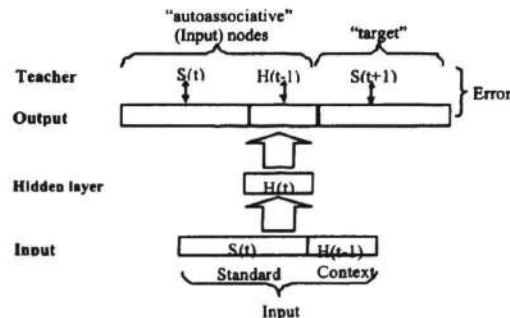

Figure 2. A Reverberating SRN (RSRN)

A dual-network architecture with self-refreshing memory to overcome catastrophic forgetting in multiple sequence learning

Ans & Rousset (1997, 2000) proposed a reverberating dual-network architecture with a self-refreshing memory to avoid catastrophic forgetting in static pattern learning. The basic dual-network architecture consists of two coupled RBP networks, denoted NET 1 and NET 2. NET 1 is the primary network that interfaces with the environment and that learns the new patterns. The secondary network, NET 2, is a "storage" network because information initially learned in NET 1 will ultimately be transferred to NET 2.

The basic principles of RSRN dual-network learning, where each of the networks is an RSRN, are virtually identical to those underlying dual-networks composed of RBP networks. Dual-network RSRNs are designed to learn multiple sequences of patterns.

Assume we have two identical RSRNs, NET 1 and NET 2. New sequences will be learned only by NET 1, while NET 2 will store the previously learned information. The learning procedure is similar to that of the basic RBP dual-network. A sequence, $S = S(0), S(1), \dots, S(n)$ is presented to NET 1. The network makes a single pass through the entire sequence, updating its weights once for each item in the sequence. This defines one learning "epoch" corresponding to one presentation of all items in the sequence in order. Next, NET 2 generates a number of pseudopatterns (e.g., 10 per learning epoch). These pseudopatterns are close to attractor states of NET 2,

which makes them particularly good vehicles for information transfer from NET 2 to NET 1. For each NET 2 pseudopattern, NET 1 performs one feedforward-backpropagation learning pass. Once this is completed, a new learning epoch starts and NET 1 makes another pass through the sequence. NET 2 generates new pseudopatterns, each of which is learned for one feedforward-backpropagation pass by NET 1. And so on. This is the awake state for an RSRN dual-network.

It is extremely important to notice that each pseudopattern generated by NET 2 is a *static input-output pattern that represents a dynamic state* (i.e., the previously learned sequence or sequences). This is what gives this system its power: there is no need to attempt to reproduce an entire pseudo-sequence that will then be interleaved with the new sequence being learned. Rather, we only need to interleave with the new sequence to be learned *non-temporal pseudopatterns*, each of which reflects (at least partially) the information in the entire previously learned temporal sequence (or sequences).

To transfer the sequence newly learned by NET 1 to NET 2, we again make use of pseudopatterns. This time the pseudopatterns are generated by NET 1 and learned by NET 2. For each pseudopattern generated by NET 1, NET 2 performs a single feedforward-backpropagation learning pass.

Overview of Simulations

We will present two simulations. The first will demonstrate the severity of catastrophic interference in multiple sequence learning in standard SRNs. The second will demonstrate that interleaving pseudopatterns (reflecting the whole previously learned sequence) with the new sequence effectively eliminates catastrophic interference.

A standard SRN network was used for the first simulation demonstrating the severity of catastrophic interference in multiple sequence learning. In the second simulation, a dual-network architecture consisting of two coupled RSRNs will be used. Each RSRN has an input layer with 100 "standard" input units (corresponding to the size of the items, $X(t)$, in the sequence) and 50 "context" units. The hidden layer consists of 50 units. The output layer consists of 150 "autoassociative" inputs that are identical to the input layer plus 100 "target" units (Figure 2).

Learning a given sequence consists of presenting it repeatedly to the network until each item in the sequence can predict the subsequent item with a pre-defined degree of precision. The network weights are updated by backpropagation once per presentation of each sequence item. A cross-entropy error function is used (Hinton, 1989; Plaut, McClelland, Seidenberg & Patterson, 1996) with a learning rate of 0.01, a momentum of 0.5 and a 1.0 bias term. All weights are randomly initialized between -0.5 and 0.5.

To create the "attractor" pseudopatterns, noise on input is "reverberated" 5 times before the actual

pseudopattern that will be used is created. Ten pseudopatterns from NET 2 are interleaved with each epoch of the sequence learned by NET 1. During transfer of the information from NET 1 to NET 2, 10³ pseudopatterns are used.

Measuring learning and forgetting

For each item, $S(t)$, of the sequence fed forward through the network, we calculate the difference between the activation values of "target" units in the output layer and the desired target item in the sequence, $S(t+1)$. We calculate this difference for each of the 100 "target" output units and count the number of output units for which the absolute value of this difference is above the learning criterion of 0.1. So, for example, assume a given item, $S(t)$, in the sequence is sent through the network. If, on the output layer, 14 of the "target" output units differ from the corresponding units of $S(t+1)$ by more than 0.1, we say that there are 14 "incorrect" units. A sequence is considered to have been learned if, for each of its elements, $S(t)$, the network produces a vector of "target" output values, each of which is within 0.1 of the corresponding element of $S(t+1)$. The overall measure of how well the network has learned (or forgotten) a sequence after a given number of learning epochs will be the total number of incorrect units over all items of the sequence.

Simulation 1: Catastrophic forgetting in multiple sequence learning

To illustrate the severity of catastrophic forgetting in multiple sequence learning, we will consider two sequences, A and B , and have an SRN attempt to learn them sequentially. The sequences are constructed as follows. Twenty-two distinct random binary vectors of length 100 are created. Half of these vectors are used to produce the first ordered sequence of items, A , denoted by $A(0), A(1), \dots, A(10)$. The remaining 11 vectors are used to create a second sequence of items, B , denoted by $B(0), B(1), \dots, B(10)$. In order to introduce a degree of ambiguity into each sequence (so that a simple BP network would not be able to learn them), we modify each sequence so that $A(5) = A(8)$ and $B(1) = B(5)$. First, sequence A is completely learned by the network. Then sequence B is learned and, during the course of learning, we monitor at regular intervals how much of sequence A has been forgotten by the network.

Fig. 3a shows the progression of the network's learning of sequence B . The number of incorrect units for each serial position of the sequence, as defined above, is shown. As expected, it is harder for the network to learn $B(2)$ and $B(6)$ since their immediate predecessors are identical and, in order to distinguish them, the network needs to additionally take into consideration the context of the preceding items in the sequence. After 450 epochs, the network has completely learned the entire sequence.

Then, during learning of sequence B , we

Figure 3. Catastrophic forgetting in an SRN during multiple sequence learning. (a): Learning of sequence *B* (after having previously learned sequence *A*). By 450 epochs (an epoch corresponds to one pass through the entire sequence), sequence *B* has been completely learned. (b): The number of incorrect units for sequence *A* during learning of sequence *B*. After 450 epochs, the SRN has, for all intents and purposes, completely forgotten the previously learned sequence *A*.

monitored the forgetting of the previously learned sequence, *A* (Fig. 3b). Initially (i.e., before the network began learning sequence *B*), it can be seen that sequence *A* was completely learned. But very early on, as sequence *B* is being learned, the network's memory of sequence *A* is overwritten. By 5 epochs after beginning to learn the sequence *B* (not shown in Fig. 3b), the network gets an average of 40% of the units of the items of sequence *A* wrong. By 250 epochs, the network's performance on sequence *A* is essentially no better than chance and, by 450 epochs, sequence *A* is completely forgotten. In short, learning sequence *B* causes severe catastrophic forgetting of sequence *A*.

Simulation 2: Catastrophic forgetting is overcome with pseudopatterns

An RSRN dual-network architecture was used with the parameters indicated above. Both networks are

Figure 4. Recall performance for sequences *B* and *A* during learning of sequence *B* by a dual-network RSRN. (a): By 400 epochs, the second sequence *B* has been completely learned. (b): The previously learned sequence *A* shows virtually no forgetting. Catastrophic forgetting of the previously learned sequence *A* has been completely overcome.

initialized to random weight settings between -0.5 and 0.5 . NET 1 then completely learns sequence *A* and then generates 10^4 pseudopatterns in order to transfer this learning to NET 2. (There are 2^{150} possible distinct states for the input layer of each network, and hence, there is a very little possibility that the random binary vectors used to produce the "attractor pseudo-input" would be actual input patterns already seen by the network.)

Now, NET 1 begins to learn sequence *B*. After each learning epoch (consisting of the entire sequence of items in *B*), NET 1 receives 10 pseudopatterns from NET 2 and does one feedforward-backpropagation pass for each of them. (The number of pseudopatterns is not related to the length of the previously learned sequences and can be varied.)

Fig. 4a shows that the NET 1 does, in fact, learn sequence *B* completely by 400 epochs. In other words, for all items in sequence *B*, all of the units in the network output are within 0.1 of the desired target

output. Notice that the sequence items $B(2)$ and $B(6)$ are learned more slowly by the network. This was, of course, expected since these two items are preceded by identical items, hence creating ambiguity having to be solved by the temporal context. During learning of sequence B , we tested the performance of the network on all of the items of sequence A . Fig. 4b shows that there is virtually no forgetting of sequence A as the network learns sequence B . In short, catastrophic forgetting has been completely overcome by the coupled system of RSRNs using pseudopattern information transfer.

Concluding remarks

We have shown that the reverberating dual-network architecture, originally proposed earlier to overcome catastrophic forgetting in non-temporal pattern learning (Ans & Rousset, 1997, 2000) can be generalized to sequential learning of multiple temporal sequences. The basic principle of interleaving internally-generated pseudopatterns from a long-term storage network with patterns from the environment being learned by a second network has been developed elsewhere (Ans & Rousset, 1997, 2000; French, 1997; Robins, 1995).

When learning multiple sequences of patterns, it turns out that interleaving simple input-output pseudopatterns, each of which reflect the entire previously learned sequence(s), reduces (or eliminates entirely) forgetting of the initially learned sequence(s).

Further, we demonstrate the power of a network architecture that allows us to produce "reverberated" pseudopatterns that are, in reality, attractors of the entire network and therefore reflect, in a highly compressed manner, the previously learned sequences.

We have demonstrated a technique that effectively allows multiple sequences to be learned consecutively. Of course, these networks can be made to forget gradually. This gradual forgetting depends on the size of the learning network and on the number, the overlap, the length and the complexity of the successively learned sequences. But the problem of sudden, "catastrophic" forgetting of previously learned sequences caused by learning a new sequence of patterns would seem to have been overcome.

Abstract

Communication is situated and it is situated in the environment, in the perception the participants have of the environment, and also in the mental representations they privately retain. This work addresses the problem of explaining the interaction between state of the physical world and mental states of actors involved in a communicative exchange. We have the goal of integrating physical world representations, such as space representation, physical co-presence of the actors and physical nature of the communication channel, with a cognitive account of communicative phenomena. We introduce the concepts of *scene*, *situation* and *scenery* for elaborating a theory for situated communication and give an account of the interaction between mental states involved in communication and the subjective representations of the state of the world.

1. Introduction

Communication and physical action are strictly connected. Since Austin's approach to Pragmatics based on speech-acts (Austin, 1962), the things one does through (not only) words, comprehension and generation of communication have been linked to the general framework of action. Conversely, the actions performed by an actor are better understood if considered as situated (Suchman, 1987; Clancey, 1998). Situations involve the physical world as well as the social world when other actors are present. The relationship between communication and action is complex. Actions performed in the physical social world are not necessarily communicative: in fact, they can either facilitate or impair communication itself, through a modification of the situational context. On the other hand, communication between actors can modify their intentions about performing actions in the physical world. Finally, the state of the physical world influences the possibility of performing actions and communicative acts.

Current theories on communication such as Relevance Theory (Sperber and Wilson, 1986) and Cognitive Pragmatics Theory (Airenti, Bara and Colombetti, 1993a; 1993b) deal with accurate descriptions of mental states and cognitive functions involved in communication. However, their applications to concrete situations is not straightforward because they do not give an account of how these mental states interact with the state of the physical world in order to produce the observed natural cases. In

particular, Cognitive Pragmatics, developing an intuition of Wittgenstein (1953), introduces the notion of behaviour game, namely a shared plan between the actors, but it gives no accounts of *how* the behaviour game is played in a concrete situation.

This work addresses the problem of explaining the interaction between the state of the physical world and the mental states of actors involved in a communicative exchange. We have the goal of integrating physical world representations, such as space representation, physical co-presence of the actors and physical nature of the communication channel, with a cognitive account of communicative phenomena. Our work is consistent with the perspective outlined by Clancey (1998) of shifting from an abstract and disembodied concept of cognition to a situated one. In one case, this approach amounts to exploiting the properties of abstract shared plans in communication, in order to enrich them with the features of concrete situated actions.

Our proposal is based on the novel concept of *scenery* that we define using the notion of a shared plan, namely a *behaviour game* in Cognitive Pragmatics terms. For an actor, to know the shared behaviour game is crucial in order to grasp the meaning of a communicative act. The *scenery* relates at the representational level context and at the level of behaviour games in terms of preconditions and possible actions.

The paper is organised as follows: Section 2 discusses situated communication in the framework of situated cognition, situated action and Cognitive Pragmatics Theory; Section 3 introduces the concepts of scene, situation, scenery and scenario; Section 4 proposes a cognitive account of situated communication and in the last Section we draw some conclusion.

2. Situated communication

Communication is obviously situated and it is situated in the environment, in the perception the participants have of the environment, and also in the mental representations they privately entertain. The Exs. 1-10 report a short fiction story that describes a long series of interactions between Alice, a professor, and Bob, a Ph.D student who aims to meet to discuss the draft of his thesis proposal. Alice and Bob communicate in a wide range of different physical environments (roads, corridors, office, elevator, cafeteria)

using different media (phone, e-mail), manipulating different objects (phones, handles, chairs, buttons, cups of coffee), meeting different people (maintenance people, cafeteria staff, a colleague). Moreover, during their interactions Alice and Bob are affected by the subjective perception they have of environments, media, objects and people, by their representations and finally by their representations of their own representations (meta-representations).

The process of communication may be theoretically described in terms of shared plans. This approach is assumed in the work of Airenti, Bara & Colombetti (1993a; 1993b) while shared plans have been proposed by Grosz & Kraus (1996). The theory of Cognitive Pragmatics is based on the idea that co-operation is the key element for the communicative interaction. It assumes that two people who communicate co-operate, and their actions are at least partly shared in order to reach a common goal. The plans by which two interacting people base their co-operation are called *behaviour games*. Plans can be seen as trees of intentions, where the leaves are specified either as terminal, precise actions, or as intentions made specific according to the context.

Behaviour games enable people to select the correct meanings to be assigned to the linguistic and extra-linguistic moves of each participant in a communicative exchange. Therefore, to understand the actor's meaning it is necessary to infer the behaviour game the actor is referring to.

Another concept adopted by Cognitive Pragmatics Theory, and which plays an important role, is *shared belief*, namely a belief that a single individual thinks of sharing with the person he is talking to. In symbols, a shared belief can be represented as follows:

SH_{AB} p

meaning that agents A and B share the belief p.

It is worth emphasising that shared belief is a subjective mental state. In other words, it may happen that A believes p to be shared by B and A, whereas B does not believe p to be shared by A and B. Shared beliefs are mental states which allow each actor to take for granted the sharing of a series of beliefs with his/her interlocutor and to use this background in order to add new beliefs. Shared belief is considered a primitive mental state of communication just like a private belief.

Given two actors, their relationship is defined as the set of playable games. The theory considers the relationship from both a static and dynamic point of view: In order to be playable a game also needs to be valid within the present state of the world. Validity refers to the whole context: physical, social and cognitive. However, the theory does not link directly relationship dynamics, validity conditions and state of the world.

From a situated perspective, the notion of communication as plan recognition and shared knowledge was targeted in the influential book by Suchman (1987). Suchman clarifies the status of plans as "an artifact of our reasoning about action, not as the generative mechanism of action"

(Suchman, 1987, p. 39), so plans do not determine actions in any strong sense. Suchman introduced the concept of situated action that describes the influence of the situation, environment included, on actions and communicative acts. However, adopting the situated cognition paradigm does not imply to accept that representations of the environment do not exist:

"Using the terms knowledge and representations synonymously, early situated cognition publications, including my own, say that 'representations are not stored in the brain'. A better formulation is that descriptions are not the only form of representation involved in cognition, and storage is the wrong metaphor for memory" (Clancey, 1998, p. 221).

The other form of non-descriptive representation, that Clancey refers to, emerges from the concept of direct perception (Gibson, 1979) supported by direct coupling between the agent and the world:

"In this interpretation of Gibson's idea of direct perception, directness means that the internal structures constitute and sustain their own space of configurations without *mediating* 'stuff' such as symbol strings representing the world. At this level of processing, outside stuff is neither brought inside directly nor mapped onto internal codes. Internal structures operate on their own changing properties. Higher levels of processing may *categorise* sensory configurations, but these are again only internal correspondences or relations between internal structures" (Clancey, 1998, p. 88).

However, the concept of situated communication introduced by Suchman emphasizes more the role of the whole set of actions performed by the actors as a situation or context for the conversational exchange, than the environment itself:

"When one takes situated language as the subject matter, however, the definition of the field must necessarily shift to communication under naturally occurring circumstances. And when one moves back far enough from the utterances of the speaker to bring the listener into view as well, it appears that much in the actual construction of situated language that has been taken to reflect problems of speaker performance, instead reflects speaker competence in responding to cues provided by the listener" (Suchman, 1987, p. 71).

Neither the shared-plan approach to communication presented above, nor the Suchman's notion of situated language are completely situated. The shared-plan approach follows the indications of a situated language provided by Suchman without considering the actions as situated or adopting her purely constructive notion of plan. The level of description is purely representational and, neither the environment nor the representations the partners have of the environment, are taken into account. On the other hand, Suchman takes into account the environment at the situated level but there is no trace of the environment in her representational notion of plan. The plan is a representation of actions that are in some sense unsituated. In other words,

both approaches lack in considering representations and meta-representations of the environment that are involved in communication and its interaction with actions.

For a complete theory of situated communication it is necessary to consider the interaction between environment and actions at all the levels: objective, directed perceived, representational and meta-representational. Considering environment and actions at each level guarantee the coherence with the situated cognition paradigm. Moreover, the approach should clarify some of the confusion generated by using the concept of "context" for all the levels.

Example

Alice is a professor. She is the tutor of Bob, a Ph.D student who is working on his thesis proposal.

```
1. >>From: Bob
   >>To: Alice
   >>Hello Alice,
   >>please find enclosed the draft of my
   >>thesis proposal.
   >>Bob
   >
   >From: Alice
   >To: Bob
   >Hi Bob,
   >the basic ideas are rather good so the
   >revision will not take long.
   >what about a meeting on Tuesday at my
   >office at 10.00?
   >Alice
   >
   >From: Bob
   >To: Alice
   >Hi Alice,
   >See you then
   >Bob
```

2. On Tuesday morning Bob is late for the meeting and he calls from his cell phone.

A: Hello

B: Hello it's Bob speaking. I'm late. Sorry, the traffic is heavy today

A: Don't worry.

3. Bob arrives and Alice is not in the office. The door is open. He waits in the corridor. Alice arrives and invites Bob to enter. They enter and Bob closes the door of the office. Alice re-opens it. They sit at the desk and they start to discuss.

4. After a while a man of the maintenance service knocks on the door. He enters saying that there is an electric failure in the building and he has to control the sockets of the room. While the man checks the room they keep on discussing.

5. The man goes away closing the door. Alice and Bob continue the discussion.

6. After a while the man comes back with a colleague saying that he has probably found the failure. They start to remove the floor tiles talking and making noise. Alice says: "Let's go to the cafeteria". Bob says: "Ok".

7. While they are going downstairs they keep on talking about the proposal but they get stuck in the elevator. Alice presses the alarm button. Bob calls security with the cell phone. While they are waiting they talk about how to get out of there and how to keep cool. Eventually the doors open.

8. They head towards the cafeteria. Alice turns left and Bob stops in the middle of the sidewalk. Alice says: "There is a shortcut to the cafeteria. We can pass through the Maths department". They keep on talking about the elevator.

9. At the cafeteria Alice meets a professor colleague. She introduces him to Bob. The professor asks Bob what is his subject and the professor asks a lot of details about his thesis. Alice says that they are going to work on it right now. The professor goes on asking questions and making suggestions. She takes her coffee cup and leads Bob to a small table with only two chairs. They start to discuss again.

10. Two cups of coffee later, Alice and Bob agree on the improvements required by the draft and end the discussion.

3. Scene, situation, scenery and scenario

We propose four different concepts (scene, situation, scenery and scenario), in order to reflect the integrate influences of environment and of actions at objective, directed-perceived, representational and meta-representational levels respectively.

The terms we adopted -scene, situation, scenery and scenario- require a justification with respect to their usual meaning. We adopted situation ("relative position or combination of circumstances at a certain moment" Marriem-Webster) in the sense introduced in the situated cognition literature (Clancey, 1998). The usual meaning of scenario refers to an hypothetical, possibly simulated, state of affairs ("an account or synopsis of a possible course of action or events" Marriem-Webster) that the reason why we reserved the word for the meta-representational level. The common-sense meaning of scene appears more concrete and real ("the place of an occurrence or action" Marriem-Webster) and we reserved it for the more objective level. Finally and in contrast with scene, we adopted scenery for giving emphasis to the representational level ("the painted scenes or hangings and accessories used on a theater stage" Marriem-Webster).

In particular, scene considers the world and its affordances. Situation considers the directly perceived world and the possible actions. Scenery considers the represented world and the plans, and finally scenario considers the meta-represented scenery and the simulated executions of plans. The last three levels roughly correspond, using Clancey terms, to structural coupling, categorical reference and symbolic interpretation (Clancey, 1998, p. 317).

A *scene* is a state of the world equipped with a set of affordances. For example, a scene can be A's kitchen and its affordances for cooking, eating, drinking, washing. From an objective point of view, given the state of the physical world, the state provides an affordance for an action if there exists an actor that can execute it in that state.

A *situation* is the direct perception that an actor has of a scene. Namely, a situation is the subjective "representation" produced by an actor A of a state of the physical world and of the actions that are possible from the point of view of an actor A. For example: A in A's kitchen perceives the room and the possibility of drinking from the tap. This means that the actor has a functional "representation" of the world that can include mental states. If the world includes mental states the situation can be perceived as shared. Note that a shared situation is not a situation in the shared knowledge but a situation that is directly perceived as shared. For example: A in A's kitchen perceives B in the room and the possibility for both of drinking from the tap.

Giving the affordances of a scene the possibility of an action will be perceived by an actor depending on her own experience of the physical world. Moreover, the possible actions from the point of view of an actor can be the result of complex processes involving, goals, plans, motivations, self-esteem, self-deceit and, perception of self, of the others and of self-in-the-world, with the relevant possible distortions.

A *scenery* is a subjective representation produced by an actor A of a state of the world and of a set of plans that it is possible to execute within the world. Given a state of the world, a plan is possible if: (i) the represented state of the world verifies the preconditions of at least one plan, (ii) the moves of the plan correspond to possible actions in the scene. The plan is said to be executable within the scenery and the scenery is said to host the plan.

For example: A retains {KITCHEN} as a scenery for the private plan [BREWING COFFEE]. An attributed scenery is a scenery attributed to another actor. For example: A entertains {KITCHEN} as attributed to B and as a scenery for the private plan [BREWING COFFEE]. A shared scenery is a scenery within the space of the shared knowledge, and a shared scenery can host private or shared plans. For example: A entertains {KITCHEN} as shared between A and B and as a scenery for the private plan [BREWING COFFEE]; For example: A entertains {KITCHEN} as shared by A and B and as a scenery for the plan shared by A and B [COOKING PASTA TOGETHER]. Finally, a shared plan can be executable in a non-shared scenery. For example: If only A knows that there is pasta in his kitchen, A entertains {A's KITCHEN} as a scenery for the plan shared by A and B [COOKING PASTA TOGETHER].

A *scenario* is a subjective representation produced by an actor A that, possibly among other things, represents a scenery. For example: A entertains [B in A's KITCHEN] as a scenario representing B who entertains {KITCHEN} as a scenery for the private plan [BREWING COFFEE] and for the shared plan [COOKING PASTA TOGETHER]. A scenario can be a rather complex representation, possibly counterfactual or dynamic. In this sense our definition is consistent with the usual meaning of a hypothetical situation.

It is beyond our present goal to show how different approaches to context fit into this framework, but it is relevant to show how each concept can be considered a sort of "context" for actions or communicative acts. *Scene* can be considered as the context in an objective sense (e.g. the room the reader is in and its affordance for reading, writing etc.). *Situation* is the perceived context (e.g. the perception of the room the reader has now, while acting, namely reading), the here and now. *Scenery* emphasize the role of representation (e.g. a representation of the room the reader have or had and of the fact that there it is possible to read a paper). Finally *scenario* is related to context in the sense of encapsulable representations (e.g. the representation the reader had while thinking in the previous two examples). Our approach is consistent with the pragmatic approach to the relationship between context and relevance proposed by Ekbia & Maguitman (2001). Earlier cognitive pragmatics accounts of context (Bara and Bucciarelli, 1998) concentrated on the role of mental states and shared knowledge in the comprehension of a communicative act (Blanzieri and Bucciarelli, 1996a; 1996b).

4. A Theory for Situated Communication

In this section we use the concepts of *scene*, *situation* and *scenery* for elaborating a theory for situated communication. The aim of the theory is to give an account of the interaction between mental states involved in communication and the subjective representations of the state of the world.

The basic assumption is that from a cognitive point of view the three levels we hypothesize co-exist and co-operate. We assume that during situated communication the actors experience a flow of situations and each of these situations inform their actions. We also assume that representations like plans and sceneries can be mentally constructed as private, shared or attributed. Finally, the actor can entertain complex meta-representations (scenarios) involving sceneries. From an objective point of view the actors executes actions on a particular scene that can be perceived by the actors in different subjective situations and represented in different subjective sceneries.

What is relevant is the relation of the scenery with the shared-plans in terms of preconditions and possible moves. For example, given an actor like Alice in the Ex.1-10, her representation of her office in a University department {OFFICE} is a scenery for the plan [TUTORING SESSION], that has its preconditions verified and its moves are possible. Both {OFFICE} and [TUTORING SESSION] are shared between Bob and herself.

The scenery represents a state of the world including the communication channel. In Ex. 1 Alice and Bob communicate by e-mail and in Ex. 2 by phone. In both cases the scenery can include the remote presence of the actors and, in the case of e-mail, the asynchronous access to the messages.

It is worth noting that in a situated perspective any attempt to produce a representation of a situation, produces a scenery or a scenario. In fact, a situation is a direct perception, not a representation. In Ex. 2 we can only suppose the shared situation Alice perceives during the phone call. It will probably include Bob, the physical world Alice perceives through the phone and actions such as talking or listening. But Bob is stuck in the traffic so he has a private situation that includes himself facing a traffic jam with waiting or walking as possible actions. In any case in the attempt of representing the situation of the other agent, each actor entertains and attributes sceneries.

A *situation* is subjective, so it can change depending on whether a change in the scene occurs or not. A change of the scene produces a change of the *situation* if the actor perceives it. In Ex. 7 Alice and Bob realise they are stuck in the elevator and that changes their *situation*. A scene can change for external reasons or by means of an action performed by the actor or by the partner. In Ex. 7 the elevator stops for an external reason whereas Alice and Bob perform two actions (press the alarm button and call security) that changes the scene.

Scenery are subjective, hence they can be unrelated to the real scene. For instance, in Ex. 8 Alice attributes to Bob a scenery of the University that does not include the shortcut and using-the-shortcut as a possible action. Obviously, sceneries may also be private representations, permitting non-standard communication such as irony or deceit. In Ex. 2 Bob could lie about the traffic and have a private scenery that differs from the supposedly shared scenery he proposes to Alice. Being a representation, the scenery can also change by means of a communicative act without any change in the scene. In Ex. 8 Alice informs Bob that there is a shortcut, information which changes his scenery {UNIVERSITY}. Finally, a scenery change can be a goal of a behaviour game. In Ex. 6 Alice and Bob start to play a behaviour game aimed to produce the scenery {THE TABLE AT THE CAFETERIA}.

A scenery hosts different plans, and conversely a plan is executable in different sceneries. For example, [SCIENTIFIC DISCUSSION] and [TUTORING SESSION] are shared plans playable in the scenery {OFFICE}. Other sceneries like for instance {THE TABLE AT THE CAFETERIA} can host some of those shared plans. A shared plan is in principle compatible with more than one scenery. Thus, a change in the scenery does affect the game, which normally will develop within the constraints of the new scenery. In Ex. 6 Alice and Bob consider [TUTORING SESSION] as playable in both {THE TABLE OF THE CAFETERIA} and {OFFICE}. A scenery is subjective, so different actors can consider different games as playable in a scenery. A more formal professor, for example, can consider

[TUTORING SESSION] not playable at {THE TABLE OF THE CAFETERIA}.

In some case a game may be played only in a specific scenery (e.g. trial in court); in other cases a game is incompatible with a scenery, hence if the scenery is activated, the game will end (e.g. smoking in a high-school toilet is interrupted by the presence of the supervisor). A change of the scenery closes the game only if the new scenery does not host the game. In Ex. 4 Alice and Bob continue to play [TUTORING SESSION] after the entrance of another actor changed the scenery from {OFFICE} to {OFFICE WITH MAINTANANCE GUY}. The new scenery hosts the game so the actors can continue to play. This is the case also in Ex. 5 where the scenery {OFFICE WITH MAINTANANCE GUYS} has changed the scenery {OFFICE}. On the contrary, the modification of the scenery {OFFICE} to the scenery {OFFICE WITH MAINTANANCE GUYS} in the Ex. 6 interrupts [TUTORING SESSION].

The actors, by modifying the partners' sceneries, shape their relationship. To settle the validity conditions of a behaviour game, is an implicit way of controlling the relation between agents. Actor A make possible for herself and B to engage in game [G], by guaranteeing an adequate scenery. In fact, proposing the scenery for a game amounts to bidding that game (e.g. driving home a potential sexual partner). In Ex. 9 Alice chooses a table that modifies the shared scenery with the annoying professor in a way that prevents the playability of a game {THREE PEOPLE DISCUSSION}. The dynamic of the relationship produces effects in the long term, also affecting the basic relationship. In Ex. 3 the actions of opening or closing the door change the scenery dramatically. Actors modify the sceneries by means of actions that can be communicative acts, as noted in Section 3.

Given the co-presence of more than two agents, for each agent the third one can be part of the scenery, or can be involved in some behaviour game. In Ex. 4 and Ex. 6, the maintenance people are part of the modification of the {OFFICE} in a very natural way. In Ex. 9, the annoying professor tries to play [THREE PEOPLE DISCUSSION] in the scenery {CAFETERIA}. Alice changes the scenery to {THE TABLE OF THE CAFETERIA} that does not host [THREE PEOPLE DISCUSSION] and the game is closed. The professor does not join Alice and Bob and so he is not even part of the scenery anymore.

In order to understand the kind of phenomena our theory accounts for, it is interesting to note that a communication exchange produces actions that are either moves of the shared-plan or actions aimed to construct, maintain or modify the shared scenery. A shared-plan theory such as Cognitive Pragmatics accounts only for the changes of the scenery produced by the execution of the shared plan. In this case it would be possible to assume the existence of a general shared plan that gives an account of the whole sequence of actions. For example, the play of [TUTORING SESSION] in the scenery {THE TABLE AT THE CAFETERIA} could be considered as the execution of a more complex behavior game than [GOING TO A TABLE

AT THE CAFETERIA FOR A TUTORING SESSION]. This operation is not plausible, in particular when the modification of the scenery is a consequence of a private plan or of an external cause that changed the scene. In fact, the idea of scenery prevents the explosion of the number of the behavior games.

5. Conclusions

We have presented a theory based on the concepts of scene, situation, scenery and scenario that gives an account of the interaction between mental states involved in communication and representations of a state of the world. The adoption of a situated cognition paradigm motivates the introduction of the concepts. Differently from precedent approaches to situated communication, we emphasize the role of the environment and of the representations agents retain of the environment.

The theory presented in this work refers to the cognitive process of two actors involved in a communicative exchange. Therefore, we do not consider the effects and phenomena produced by the interaction of three or more people. This requires further work in order to bridge the gap between cognitive processes involved in communication and phenomena studied by social psychology.

Ah-Ha, I Knew It All Along: Differences in Hindsight Bias Between Insight and Algebra Problems

Abstract

The present study investigated the role of restructuring in the solution of insight and incremental problems. Participants were presented with a series of insight and algebra word problems in a hindsight bias paradigm (Fischhoff, 1975). Those who solved the insightful problems correctly showed increases in importance ratings on the key problem components. However, no increases in importance ratings were detected for the key problem components of algebra problems. These results are consistent with theories that propose that representational restructuring plays a fundamental role in the insightful problem solving process (Davidson & Sternberg, 1984; Ohlsson, 1992).

Restructuring and Insightful Problem Solving

A number of researchers have suggested that insight problems may be solved in a qualitatively different manner from incremental or analytic problems (Duncker, 1945, Davidson & Sternberg, 1984, Metcalfe & Wiebe, 1987, Ohlsson, 1992). For example, when Metcalfe and Wiebe (1987) had subjects make feeling of warmth ratings while solving algebra and insight problems, they found that while solving algebra problems, subjects' warmth ratings steadily increased towards the time of solution; whereas during the solution of insight problems subjects' warmth ratings remained low and suddenly increased right before they solved the problem. These results suggest the processes for solving insight problems are different from the systematic or analytical processes used for incremental problems. However, this only represents the *suddenness* of the insightful process and does not shed light on the causes of the solution patterns.

It has been suggested that insight problems differ from incremental problems in that the nature of the solvers' experience causes them to construct a representation of the problem that cannot lead to the correct solution (Duncker, 1945, Davidson & Sternberg, 1984, Ohlsson, 1992). In order to come to the correct solution, solvers must restructure their original conception of the problem. Proposed evidence for restructuring in insight problem solving has come from a wide range of empirical findings. For example, Dominowski and Buyer (2000) found decreases in re-solution time for those who correctly solve insight problems but not for those who were simply shown the answer. Knoblich, Ohlsson, and Raney (2001)

analyzed eye movements during the solution of matchstick arithmetic problems and found evidence for impasses followed by increased fixations on components of the problems that were key to solution. Durso, Cornelia, and Dayton (1994) attempted to find an independent measure of restructuring by statistically modeling successful and unsuccessful problem representations after the problem solving session. They found that successful solvers representations centered on concepts key to the nature of the solution, whereas non-solvers representations centered on the principle characters in the story problem, which were not relevant to the solution.

These empirical studies suggest an insight problem solving process that involves the restructuring of the mental problem representation. However, these studies fall short of proving the existence of a restructuring process because they fail to directly measure representational change before and after solving across an individual and fail to compare problems that involve incremental solutions to the problems proposed to elicit insightful solutions. What is needed is an independent measure of restructuring in order to test theories that predict an insight process involving restructuring against theories which do not predict restructuring in any problem solving process (such as Weisberg's nothing special view, 1986). Furthermore, this method must be able to directly test whether more restructuring is involved in insightful than incremental problem solving. The present study uses a hindsight bias paradigm to produce an independent measure of the amount of restructuring involved in solving different types of problems.

Hindsight Bias

Hindsight bias is the observation that people with outcome knowledge of a situation falsely believe that they would have predicted the correct outcome (Hawkins & Hastie, 1990). Fischhoff (1975) originally developed the basic paradigm. He had people read a narrative of a situation with or without receiving the outcome and then had them rate the probability of alternate outcomes as if they had no knowledge of the outcome. The general finding is that people with outcome knowledge unknowingly rate the outcome they were told as more probable than alternatives, as if they "knew it all along." Individuals who receive outcome knowledge also rate the sentences in the narrative that support the given outcome

as more important than those that do not, even though they are asked to ignore the given outcome. This same effect has also been shown in within-subject studies in which participants are asked to rate outcomes before they receive outcome information, and then asked to reproduce their original questionnaire ratings after receiving outcome information (Fischhoff & Beyth, 1975). Most research suggests that hindsight bias is not due to motivational factors but involves cognitive processes that automatically restructure one's situation representation to accommodate the new information, leaving individuals unable to access or reproduce their original representation (Hawkins & Hastie, 1990).

This leads to the hypothesis that processes that cause more restructuring will lead to more hindsight bias. Restructuring theories of insightful problem solving make clear predictions about the nature of hindsight bias for insightful problems. If correctly solving insight problems involves restructuring of the problem space to come to a solution, then those who correctly solve insight problems should show hindsight bias on the problem components that are key to solution. However, those who fail to correctly solve the insight problems should not show any hindsight bias on those components.

If this restructuring occurs only as a result of an insightful problem solving process, then being shown the solution should not lead to hindsight bias of a similar nature to those who solve on their own. Algebra problems should be solved in an incremental fashion. Therefore, restructuring theories of insightful problem solving would predict no hindsight bias on the key components of algebra problems regardless of correctness of solution or being shown the answer. Finally, the "nothing special" or gradual transformation theory of insightful problem solving (Weisberg, 1986) predicts no differences in between insightful and incremental solution processes. Therefore, this theory would predict no difference in hindsight bias between insight and algebra problems or those who come to solution, and those who do not come to solution but are shown the correct answers.

The present study consisted of two sessions. Participants received a series of insight and algebra word problems. During session one, Ss first were asked to read through each problem carefully and rate each component of the problem on its importance in finding the solution. Then they were asked to attempt to solve each problem. Following the solution phase approximately half the Ss were shown the correct solution. After a one week interval Ss returned for the second session. At this time they were asked to attempt to remember their original importance ratings for each of the problem components. Hindsight bias was measured as the change in importance ratings between the two sessions, in favor of relevance for solution.

Methods

Participants. One hundred twenty eight introductory psychology students participated in this study to fulfill a class requirement. They were run in groups of 3 to 12.

Design. This study consisted of two one-hour sessions separated by a one-week interval. During the first session Ss rated the importance of the problem components of several insight and algebra problems. Next they attempted to solve each problem. After attempting to solve, half the groups were shown the solution. After a one-week interval Ss returned and were asked to reproduce their original component importance ratings. This resulted in a 2 session rating (session 1, session 2) X 2 shown answer (Yes, NO) X 3 solution type (no solution, incorrect, correct) X N components (varies by problem) mixed design. Session rating and problem components were within-subject variables, while shown answer and solution type were grouped between subjects.

Materials and Procedure. Participants completed the SIQ booklet first. The SIQ booklet consisted of six insight problems and four algebra word problems. Ss were instructed to carefully read each problem, but not to attempt to solve the problems. Instead, Ss were asked to rate each sentence or component of the problem on how important it is in finding the solution to the problem. Each sentence or component of the problem was listed one at a time followed by a rating scale that consisted of a 7.3 cm continuum. The far left side of the continuum was marked as representing "very unimportant," while the far right side was marked "very important." Participants were instructed to make a mark anywhere on the continuum that best represented their opinion of the particular problem component. Participants were allowed to work through the questionnaire booklet at their own pace but were allowed no more than 15 min. to complete all the ratings. The experimenter periodically reminded participants not to attempt to solve the problems throughout the rating phase. These ratings are the session 1 importance ratings.

Next participants completed the problem-solving packet (SIS). The SIS booklet presented the same 10 problems, each on its own page. Ss were instructed to attempt to solve each problem and that they would be given three minutes to complete each problem. The directions instructed the Ss to show all work, circle their final answer, and if necessary explain the solution using a few short sentences. Ss were instructed to work through the booklet in order, stop working on a problem at the experimenter's signal, and wait until the experimenter's signal to begin the next problem. Ss were given 3 min. to work on each problem. The Ss performance each problem was used to assign participant into one of three solution type groups (no answer, incorrect, correct) for each problem.

After attempting to solve all the problems, half of the groups were dismissed (shown answer no). The other half (shown answer yes) were shown step-by-step outlines of the solutions of each of the problems on an overhead projector. The experimenter read a script that explained each answer. Each problem explanation took approximately 1 min. At the conclusion of session 1 Ss were asked not to discuss the details of any of the

problems they saw or their solutions with anyone else in the Subject Pool and dismissed.

Session 2 occurred exactly one-week later in the same room at the same time. Ss were first issued the second session questionnaire packet (S2Q). This packet was identical to the first except that the participants were asked to attempt to reproduce their exact component importance ratings from the first experiment. These ratings are the Session 2 importance ratings. They were once again allowed to work through the booklet at their own pace but had no more than 15 min. to complete the entire memory test. Then, Ss once again attempted to solve each problem in the same manner as in session 1. Finally, participants were debriefed as to the nature of the study and once again asked not to discuss the study, problems, or solutions with anyone else in the Subject Pool.

Table 1: Number of Participants Per Cell by Problem.

Sol. type	Shown Answer Yes			Shown Answer No			Total
	NA	IN	CO	NA	IN	CO	
Train	14	27	30	11	16	30	128
Age	20	25	26	18	20	19	128
Triangle	22	23	26	20	17	20	128
Cups	6	23	24	11	26	25	115*

Note: NA = No Answer; IN = Incorrect; CO = Correct

* 13 Ss had to be dropped from this problem for missing data and/or marking the top importance level for all components on both sessions.

Results

Two algebra and two insight problems from the set of problems were chosen for the problem component analysis. These problems were selected on the basis of two criteria. The first criterion was due to a conceptual constraint. Each problem component or individual sentence had to contain only either information that was key to the solution or not. In other words, any one component of a problem must have been mutually exclusive from the other components and contain unique information that was only interpretable as important or unimportant depending on one's interpretation of the problem. The second constraint was a practical constraint. Each problem had to result in a moderate solution rate such that there would be a number of individuals in each of the solution type groups, and result in a similar number of individuals for each solution type across "answer shown" groups. The two insight and two algebra problems that best met these criteria were selected for analysis. The problems are presented in Figures 1-4, problem components are indicated by lower case letters. The number of participants in each cell for each problem is listed in Table 1.

Problem Component Ratings Problem component scores were coded by measuring the distance of the participants' mark on the continuum from the left end with a ruler. Lower scores indicate that a sentence or component in a problem was perceived as of little

importance toward the correct solution, while higher scores indicate that a sentence or component in a problem is perceived of great importance in coming to the correct solution. Hindsight bias is the increase of an individual's importance rating for a solution-related problem component between the first and second sessions.

Restructuring theories of insightful problem solving predict that on insight problems, initial component importance ratings should reflect solvers' activation of an inappropriate problem representation. Those who overcome the impasse and correctly solve the problems need to restructure their representation of the problem to activate the correct operators or components for solution. This new representation should lead to hindsight bias in the importance ratings for the key components of the problem.

Those who fail to solve the problem should show no hindsight bias for key problem components, and may even increase their importance ratings for the original inappropriate components of the problem. In algebra problems no restructuring of the problem representation is necessary to come to solution, therefore no change in representation of the problem should be evident in the hindsight bias measures of algebra word problem components.

a) Two trains leave the same station at the same time. b) Each has enough fuel for a 2000 mile trip. c) The trains travel in opposite directions. d) One train travels 60 miles per hour, and the other 100 miles per hour. e) In how many hours will the trains be 800 miles apart?

Figure 1: Train Problem (Problem Type: Algebra)

a) Ann is twice as old as her son. b) They were both born in June. c) Ten years ago Ann was three times as old as her son. d) What are their present ages?

Figure 2: Age Problem (Problem Type: Algebra)

b)O c)O
d)O e)O f)O
g)O h)O i)O j)O

Figure 3: Triangle Problem (Problem Type: Insight)

The picture below is of six glasses. The first three contain liquid. Describe how you could make it so no two glasses containing liquid are next to each other, while keeping three of the six glasses full. To do this, you are only allowed to move one glass.

Figure 4: Cups Problem (Problem Type: Insight)

Train Algebra Problem The train problem (see Figure 1) involves constructing and solving equations in order to find how many hours it will take for two trains to be 800 miles apart. To solve this problem one must use information from sentences (components) A, C, D, and E. These sentences are therefore the *key components* in this problem. To investigate whether restructuring was involved in solving this algebra problem, a 2x5x2x3 (session x component x answer given condition x solution type (no solution, incorrect solution, correct solution)) ANOVA was conducted. Evidence for restructuring as measured by hindsight bias is revealed by interactions involving the session variable. Specifically, an increase in importance ratings on key components across sessions (initial rating vs. second rating) for those who correctly solve the problem is evidence for restructuring.

This analysis revealed a significant session x component x solution type interaction $F(8, 484) = 2.69, p < .05, \eta^2 = .04$. Follow-up analysis revealed that this small interaction was due to significant *decreases* in importance ratings on component D, and E for those who answered incorrectly and were shown the answer ($t(26) = -3.71, p < .01$, & $t(26) = -2.78, p < .01$ respectively). There was also a significant decrease in importance rating on component E for those who answered correctly and were shown the solution, $t(29) = -3.21, p < .01$ (see Table 2). If restructuring of the problem representation was necessary to solve this algebra problem one would expect to see *increases* in importance ratings on components A, C, D and E for those who correctly solve. This was not the case. Clearly there is no evidence of restructuring in those who solved the train algebra problem.

Age Algebra Problem The Ann and Son problem involves constructing equations from the given information to calculate Ann and her son's present age. Sentences (components) A, C, and D are key components for this problem (see Figure 2). To investigate whether restructuring was involved in solving this algebra problem, 2x4x2x3 (session x component x answer condition x solution type) ANOVA was conducted. This analysis once again revealed a significant session x component x solution type interaction $F(6, 353) = 3.35, p < .05, \eta^2 = .05$. However, follow up analyses revealed no significant differences between session 1 and session 2 ratings for any of the components in any of the groups (see Table 2). This interaction was most likely caused by the trend toward hindsight bias on component C by those in the correct solution/not given answer condition, and by a trend towards a *decrease* in importance ratings on component D in the incorrect/ shown answer group. However, interaction was small in effect size. These unsystematic trends are weak evidence for restructuring. Therefore, once again, we find no clear evidence restructuring in the solution of algebra problems.

Cups Insight Problem In order to solve this problem, one must pick up the glass in position B and pour the liquid into the cup in position E. Therefore, B and E are the key components of this problem. The insightful

process theories would predict that the initial representation should be biased against viewing cup E as being key in finding the correct solution. This leads to the prediction that importance levels should increase for the two key components for those who correctly solve, while those who do not correctly solve should not show hindsight bias on only the two key components.

To investigate whether restructuring was involved in solving this problem, a 2x6x2x3 (session x component x answer condition x solution type) ANOVA was conducted. This analysis revealed a significant session x component interaction, $F(5, 545) = 4.7, p < .05, \eta^2 = .02$. Follow-up analysis revealed significant increases in importance ratings for both key components B ($t(119) = 3.85, p < .05, \eta^2 = .11$) and E ($t(119) = 2.10, p < .05, \eta^2 = .03$) across all participants. Even though a survey of the means (see Table 4) gives the impression that the groups that solved the problem correct are driving this effect, a significant interaction involving solution type was not detected. This result tends to follow the predicted pattern of hindsight bias that would be expected with regards to restructuring accounts of insightful problem solving, and stands in contrast to the algebra results that showed no evidence of restructuring.

Triangle Insight Problem To solve this problem, one must move the corner three circles around one position in order to make the triangle point down. The insightful process theories would predict that the initial representation should be biased towards viewing the array as a triangle and therefore solvers will inappropriately view the point of the triangle, or the top three circles, as more important. In order to solve, individuals will need to restructure their representation of the middle circles of the triangle as invariant whether the triangle points up or down. Therefore, the corner circles A, G, and J, are the key components for solving the problem (see Figure 3).

To investigate whether restructuring was involved in solving this insight problem, a 2x10x2x3 (session x component x answer condition x solution type) ANOVA was conducted. This analysis revealed a significant session x component interaction, $F(9, 1098) = 4.05, p < .05, \eta^2 = .03$; a significant session x component x answer condition interaction, $F(18, 1098) = 2.04, p < .05, \eta^2 = .01$, and a significant session x component x solution type interaction, $F(18, 1098) = 1.91, p < .05, \eta^2 = .03$. Follow-up analysis found significant increases in importance ratings, or strong positive trends, on each of the key components for those who successfully solved the problem regardless of whether they were shown the answer (see Table 5). This evidence supports the idea that those individuals who solved correctly had a different (more appropriate) problem representation on their second encounter with the problem.

Other significant increases were found on components D and E (both unimportant for finding correct solution) for those who came to no solution and did not receive the answer. In the groups that received the answers but did not find the correct solution, increases in importance ratings were detected on the entire bottom row of circles

(G through J). These findings suggest that being shown the solution to an insight problem can lead to a shift in representation. However this shift is not exclusive to the key problem solving components.

Discussion

These results suggest that hindsight bias can be used as an independent measure of the restructuring involved in solving different problems. These results demonstrate some of the characteristics predicted by insightful problem solving theories that involve mechanism of sudden restructuring of one's problem representation in order to come to solution (Duncker, 1945, Davidson & Sternberg, 1984, Ohlsson, 1992). Although all of the predicted interactions on insight problem component ratings were not found to be significant, there was evidence of an increase in importance ratings on key components in insight problems and not on algebra problems. Also there was evidence that these increases in importance ratings occurred in groups that had successfully solved the insight problem, regardless of whether they were shown the correct solution. The results on the insight problems contrast with those for the algebra problems, which showed little evidence of any increases on importance ratings on the key components. In examining the results it is clear that individuals initially were able to recognize which components of the algebra problems were key in solving the problem. However, even though all individuals were able to correctly report the importance of the key components, many still failed to correctly solve the algebra problems. This suggests that the locus of difficulty for the algebra problems did not lie in the representation.

While all the predicted interactions on the insight components were not found, it is helpful to keep in mind that this was a very stringent test for hindsight bias. The participants in this study were not asked to re-rate the questions during the second session of the experiment. They were asked to "reproduce" or remember their original ratings. It has been estimated that 2/3 of participants are actually able to remember their original rating in this type of within-subjects design (Fischhoff & Beyth, 1975). Even though steps were taken to prevent this (ex. rating were done on continuums instead of Likert scales, one full week between sessions) this surely may have affected the final outcome. Also, all theories of insightful problem solving agree that restructuring is far more likely when subjects are naïve to the problems. In this design there was no way to separate out those who had experience with the problems and were able to solve through some other method than restructuring (i.e. memory search). On the same note, it may be possible that individuals did not have the expertise in algebra to solve the problems in a totally incremental fashion. In this design there was also no way to separate out those who experienced *partial insights* while solving the algebra problems (see Ohlsson, 1992). These factors may have also confounded the hindsight bias results. Despite all of these issues, there was clear evidence for differential amounts and patterns of hindsight bias between insight

and algebra problems. Currently we are in the process of conducting more detailed studies using the hindsight bias paradigm on a wider range of problems, as well as using this method to investigate the role of impasse in the insightful problem solving process.

Acknowledgements

This research was completed as part of a Masters degree requirement at the University of Illinois at Chicago. Special thanks to Thieu Dang, Trina Kershaw, Amy Brodhead, Josephina DeAnda, Monica Nemiec, and Yessenia Cervantes for the assistance in running participants, and coding/entering data.

A Neurocognitive Model for Students and Educators

Michael Atherton (athe0007@umn.edu)

Department of Educational Psychology, 178 Pillsbury Drive SE
Minneapolis, MN 55455 USA

Abstract

Computer metaphors for cognitive processes have become dated and new models are required to help college students and classroom teachers interpret research in the neurosciences as it begins to impact the fields of education and psychology. A model of cognition using a metaphor of neural activation is presented and supported by finding in the neurosciences.

Introduction

In 1986, Rumelhart and McClelland published *Parallel Distributed Processing* and revolutionized our conception of memory and thought processes. Their introduction of neural networks as a model of memory served as a starting point for the growth of neurologically based computational models. Today, cognitive and computational neuroscience research is continuing to enhance our understanding of cognition. However, while the neurosciences influence how researchers comprehend thought processes, there has been little change in the models we teach students in introductory psychology and education classes. What is needed are models that provide students with a framework for understanding the neural bases of cognition and are at the same time simple to communicate and comprehend.

The Need for a New Model

The information processing model of cognition has provided us with many useful characterizations of mental functions: sensory registers, short-term memory, working memory, and long-term memory. Its ultimate failure has been its inability to integrate these characterizations with research findings in attention, imagery, and reasoning to form a comprehensive model of cognition. This failure is caused in part because theoretical descriptions of behavior are weakly constrained and allow multiple valid interpretations of the same phenomenon. This variability in description has fractionalized cognitive research into narrow domains focused on particular aspects of mental activity. Thus, students study cognitive topics such as perception, memory, and learning that have little relation to each other, leaving them without an associative framework.

Another problem with the information processing model is that its conceptualizations of thought processes often clash with research findings in contemporary neuroscience. It is now clear that

memories are not compartmentalized into boxes or transferred from location to location as they are in a computer. Such characterizations can lead students to inferences that are not always valid, and in education such inferences can lead to instructional methods that are not always effective. In the past ten years technological and methodological advances in the neurosciences have produced a wealth of research results that have greatly increased our understanding of the biological underpinnings of cognition. This research has already impacted traditional cognitive theories (Miyake & Shah, 1999), but what is needed are not models that have been updated to account for the new data. What is needed are models that are built from the neuron upwards, rather than from behavior downwards. Such models stand a better chance of providing an internally consistent integrative framework for understanding cognitive research.

This revolution in orientation from top-down to bottom-up analyses represent a fundamental shift in the science of cognition and as Kuhn (1962, p. 109) has pointed out, "...when paradigms change, there are usually significant shifts in the criteria determining the legitimacy both of problems and of proposed solutions." Thus, we see major issues in popular culture such as the division between mind and body become irrelevant as old axioms are rejected and new ones formed (Crick, 1994). This paradigm shift is well underway in the field of psychology (Gazzaniga, 1998) and cognitive science, but has been hampered in education by the dubious application of the neurobiological research; to wit, "brain-based learning" has become the phrenology of the new century (Bruer, 1999a). The fact that such questionable conceptualizations of cognitive neuroscience are being actively marketed to educational practitioners begs for models that are well grounded by research in the neurosciences. The purpose of this paper is to present one such model in the hope that it will inspire discussion within the educational community. I will begin by presenting the model as it might be presented to students and the following section will review the scientific justification for the model.

The Model

The cognitive model presented below is a synthesis of the current research in the neurosciences. It is proposed as a descriptive theory in which the complexity of some neurological processes has been simplified for

pedagogical advantage. For the most part I have tried to avoid issues that are the subject of on going debate, however I do make theoretical assumptions at some points to create an internally consistent model. Readers should keep in mind that what follows is a hypothetical description and that some, or many, aspects of the model have yet to be verified empirically.

Structure

Neurons The fundamental processing element in the brain is the neuron. A neuron is a cell that consists of dendrites, a body, and an axon. Signals are transmitted between neurons by chemicals called neurotransmitters at junctions between dendrites and axons called synapses. When neurotransmitters pass across a synapse from the axon of one cell to the dendrite of another they cause chemical changes in the dendrite and the body of the neuron and have an effect on the physical structure of the synapse. When a sufficient number of signals infringe on a neuron, they cause that neuron to release neurotransmitters at the synapses of its axons. When a neuron is in such a state, is receiving signals and releasing neurotransmitters, it is said to be *active*. The signals that a neuron sends can have either an excitatory and inhibitory effect. Excitatory effects cause other neurons to increase their activity; inhibitory effects prevent neurons from becoming active, i.e., from sending signals to other neurons.

Networks Neurons are highly interconnected; a single neuron can have thousands of synapses connecting to thousands of other neurons. Neurons that activate in common are linked together by synapses into networks. Networks of neurons can be local to a particular location in the brain, or they can be global and distributed across different regions of the brain. Local networks can be confined to an area a thousandth of an inch, whereas global networks can extend over distances of several inches and be comprised of multiple local networks. Networks can also be classified as task networks or control networks. A task network performs a specialized function such as the processing of the orientation of a line, of a color, or a phoneme. Task networks are also involved in more complex processing, such as the graphical representation of a word, or a human face. A control network, on the other hand, regulates the processing of a task network via connections that inhibit or activate neurons. This activation or inhibition by control networks functions to maintain, select, monitor, sequence, or integrate activity within task networks.

Control networks can be either local or global. Local control networks regulate task networks and are not necessarily physically distinct from them, but instead maybe spatially intertwined. Global control networks serve to regulate the activation between multiple task

networks. Within the brain local control and task networks are generally located in regions known as the occipital, parietal and temporal lobes. Global control networks are generally located in the frontal lobes (Figure 1). General cognitive functions, such as auditory or visual processing that are executed by task networks are localized to particular areas in the brain such as the temporal and occipital lobes. While task and control networks maybe localized to different regions this does not mean that they are disconnected, rather as a general rule all classes of networks are highly interconnected.

Figure 1: Global control networks are located in the frontal lobes; local task networks are located in the occipital lobes, parietal, temporal lobes.

Processes

With the neural and network structure outlined above traditional cognitive processes can be redefined in relation to their neurological processes. It is assumed that since thought processes are a function of brain activity, all of the concepts in traditional cognitive psychology can be redefined within such a framework. This paper covers fundamental topics such as learning, basic forms of memory, and attention.

Learning Learning is the process of making enduring changes in the relationships between neurons through the modification or creation of synapses. Learning is the intrinsic result of sensation, perception, thought, physical action, or the result of intention. Since thought or perception requires the activation of neurons, activation induces a change in the physical state of the synapses involved. When these changes are retained over time they form memories; when ephemeral they, along with the biochemical and electrical processes that cause them, form thoughts. Not all neurons exhibit the same properties; neurons and synapses differ in the rate at which changes are retained. Thus, long term physical changes in neurons located in areas that process sensory stimuli would occur slowly, whereas

changes in neurons storing life experiences would occur more rapidly.

Memory A memory is a stored pattern of synaptic connections within local networks or across an interconnected network of neurons. A single neuron might contribute to several memories by releasing varying amounts of neurotransmitters depending on how it is activated, but the activation of a memory requires interactions between neurons. That is to say, no one specific memory is stored in a single neuron, rather a memory is distributed across a network of neurons as a pattern of synaptic relations. Additionally, several memories may be stored in the same network by different patterns of synaptic connections.

Traditional cognitive models have identified different functional categorizations of memory. Traditionally, the major categorizations have been short-term, working, and long-term memory. Within the current model each of these can be defined by neurological processes. Short-term memory represents the dynamic patterns of activation in networks across the brain. These patterns of activation arise from transitory chemical and electrical properties of neurons lasting a few seconds. Working memory represents a combination of short-term memory processes along with other chemical and transient physical synaptic changes lasting several minutes. Long-term memory represents physical synaptic changes lasting from minutes to days, weeks, or years, thus long-term memory is viewed as scaled physical changes in synapses on a continuum across time, rather than as discrete storage locations. Physical changes in synapses may revert to a previous state in some types of neurons if not reactivated.

Memory Capacity Traditional short-term or working memory has been shown to have a limit on the number of items that can be held in consciousness simultaneously. In the current model memory capacity is regulated by both the physiological and structural aspects of neural networks. Physiologically neural activity is limited by the production and transmission of neurotransmitters and rate at which cells can produce signals. While neurophysiology places a limit on what can be held in neural networks at any single point in time, working memory capacity can be increased by adapting the underlying network structure for particular types of memories. Thus, experts in specialized areas such as chess have better working memory for meaningful configurations of pieces than do novices because they have tailored synaptic patterns to particular stimuli.

Forgetting In short-term memory forgetting occurs as cells stop sending signals and the concentration of

neurotransmitters decays and returns to baseline. This process normally occurs within seconds unless activation is renewed. In long-term memory forgetting may occur when physical synaptic changes decay or as activation overlays new synaptic patterns over existing ones causing interference.

Attention Attention is the modulation of activation in a network by a control network. Modulation takes the form of either a rise or a reduction of activation. This modulation can occur across widely separated regions in the brain or locally within a specific part of the brain. Attention can be focused in different regions when a global control network or a combination of global control networks modulates activation within local task networks. Attention is a process which occurs when specific stimuli or tasks require specialized processing. Attentional processing may be required to keep particular memories active (maintenance), discriminate between similar stimuli (selection), when anticipating environmental stimuli (monitoring), when planning a particular action (sequencing), or when it is necessary to coordinate multiple responses (integration). Attentional modulation may be initiated from the bottom-up by neural signals originating in task networks that then activate global control networks, or from the top-down when global control networks execute a motivational goal.

Attention can also be focused in specific areas in the brain by local control networks without modulation by global control networks. This can occur within task networks when a local control network modulates activation. Many of the same functions executed by global control networks (maintenance, selection, monitoring, and sequencing) can be also be performed by local control networks. The process of transferring control from a global control network to a local one is called automation. Automation occurs by adjusting synaptic connections within a task network so modulation of activation is stimulated and responded to by activity within the task network. This adjustment of synaptic connections in task networks occurs through attentional modulation or by sensory activation. This is generally a slow process and may require both focused attention and repeated practice.

Retrieval from Memory Memory retrieval in traditional psychology is divided into two general classes: recall and recognition. Recall involves the explicit retrieval of information from memory. Recognition, on the other hand, only requires knowing if something has been previously encountered. In the current model retrieval is defined as the reactivation of a previously active network. Recall differs from recognition in that recall requires full activation of a local network by a global control network in a top-

down process, whereas recognition involves signaling a control network that some activation occurs in some local network and can occur as either a bottom-up or a top-down process.

An Activation Metaphor

Being able to imagine how thought processes occur in the brain can help teachers plan lessons and can also help undergraduate students tie together disparate concepts in psychology. The current model lends itself to an activation metaphor so that students can picture thought processes as dynamic intensifying and receding patterns of activation, much as neural activation is depicted by differences in blood oxygenation levels in the brain by functional magnetic resonance imaging (fMRI; see Figure 2).

Figure 2: The brighter areas identify implied patterns of neural activation as detected by fMRI.

The processes of reading provides a good example of how levels of activation can be used to represent thought processes. When a word is first presented the visual areas in the rear of the brain become active. Activation is next seen in the word form area on the lower left side of the brain (Cohen, et al., 2000). At about this time there is an interaction between control networks in the left frontal areas and task networks in the lateral and posterior regions. There appears to be separate control networks for different aspects of reading such as grammar and those relating to semantics and these different networks appear to control specific task networks (Bokde, Tagamets, Friedman, & Horwitz, 2001; Poldrack, et al., 1999). Reading progresses as an interplay of activation between the control and task networks performing the functions of phonics, grammar, and semantics. Levels of activation in these areas can increase or decrease depending on the complexity of the task, when syntactic errors are encountered, or when semantic anomalies occur. Comprehension of longer passages of text appears to activate control and task networks on the

right side of the brain (Robertson, et. al, 2000; St George, Kutas, Martinez, & Sereno, 1999).

Figure 3: Idealized activation patterns during reading. (A) Displays the brain at rest. (B) Activation of visual areas. (C) Activation of the word form area. (D) Initial activation of frontal control networks. (E) Additional activation of phonological and semantic areas. (F) Interplay between control and task networks. The upper line indicates areas associated with phonological processing; the lower line with semantic processing.

While patterns of activation can provide an understanding of interacting networks, attention, short-term and working memory it should be kept in mind that long-term memory is the result by physical changes and is not necessarily reflected directly in the activation patterns, i.e., long-term memory is resultant effect of the activations.

Supporting Evidence

While some aspects of the model have not yet been verified empirically, most of the concepts are accepted by at least a portion of the neuroscientific community. In this section I will outline some of the research supporting the model.

The view that the changes in synaptic junctions are at least one of the major components of learning has been accepted for some time (Collingridge & Bliss, 1995; Larkman & Jack, 1995) and current research has been supportive of this hypothesis (Kennedy, 2000; Matus, 2000), however the exact mechanisms underling learning (Barinaga,1999) and forgetting (Berman & Dudai, 2001) remain the object of ongoing research. The assumption that learning occurs through the

formation of new synapses (Klintsova & Greenough, 1999) is more debatable and has been questioned by Goldman-Rakic a leading researcher (as cited in Education Commission of the States, 1996, p. 11). A far more controversial conjecture has been the formation of memories via the creation of new neurons. Recent publications have indicated that, contrary to previous doctrine, new neurons are created after birth (Gould, Tanapat, Rydel & Hastings, 2000; Shankle, Rafii, Landing, & Fallon, 1999) and may also be involved in the formation of memories (Shors, et al., 2001), but these conclusions have been challenged (Kornack & Rakic, 2001).

The interpretation of short term memory as dynamic biochemical and electrophysiological processes is hypothetical, but research has shown that transmission between nerve cells is separable into different chronological processes (Greengard, 2001). The concept of working memory extending over longer periods of time was introduced by Ericsson and Kintsch (1995) and is supported by neuroscience research showing dendritic changes occurring on a continuum ranging from seconds to days (Antonova, et al., 2001; Wong & Wong, 2001).

The existence of large scale modularity in the brain has been recognized since the 1800s when it was discovered by Broca and Wernicke (Gazzaniga, Ivry & Mangun, 1998). The high degree of specificity in local networks has been a more recent finding. Spatially limited networks, characterized by the current model as task networks, have been found to subserve functions such as: the detection and orientation of lines (Hubel & Wiesel, 1968), the motion of patterns (Movshon, Adelson, Gizzi, & Newsome, 1985), the recognition of objects (Tanaka, 1997), and the recognition of faces (O'Craven & Kanwisher, 2000). The existence of global networks is widely accepted in the neuroscience and cognitive communities (Stuss & Alexander, 2000; Varela, Lachaux, Rodriguez, & Martinerie, 2001); as is the recognition of networks that modulate attention, although agreement on the specific mechanisms of modulation may differ (Driver & Frith, 2000; Posner & Rothbart, 1998; Rogers, Andrews, Grasby, Brooks & Robbins, 2000). The concept of integrative networks can be thought of as a reformulation of accepted views of the functioning of working memory in the frontal lobes (Duncan & Owen, 2000; Levy & Goldman-Rakic, 2000), but once again, the opinions on the exact organization and mechanisms differs.

Conclusions

Given the advances in the neurosciences it is now both necessary and advantageous to formulate cognitive models based on neurological processes rather than on metaphors derived from other disciplines. Inevitably, we will see many new comprehensive models linking

cognition to its neurological foundations. This paper represents an initial attempt to formulate such a model in the hope that it can be used as a pedagogical tool for students and teachers.

Abstract

Previous studies (e.g., Rieser, 1989) have established that physical rotations result in effortless updating of spatial information contained in visually perceived scenes. The present experiment provided evidence that this is not the case for scenes that are encoded through texts. Performance was better under the perspective that the scenes were learned than under novel perspectives, regardless of whether rotations were physical or imagined. In addition, the experiment suggested that the orientation of the ecological frame affects spatial performance even when people operate in a purely represented framework.

Introduction

Various studies (e.g., Chance, Gaunet, Beall, & Loomis, 1998; Klatzky, Loomis, Beall, Chance, & College, 1998; Rieser, Guth, and Hill, 1986; Simons & Wang, 1998; Wang & Simons, 1998) have established a link between active locomotion and the successful spatial updating of previously viewed scenes. Researchers have proposed that spatial updating is carried out by an internal mechanism that constantly computes the relative locations of objects as people move in the environment (Wang & Spelke, 2000). Indeed, when people change their position within an environment they seem to experience little difficulty with keeping track of how the locations of objects change, even when the objects are no longer in view (Attneave & Farrar, 1977; Fukusima, Loomis, & Da Silva, 1997; Loomis, Klatzky, Colledge, Cicinelli, and Pellegrino, 1993). In fact, responding to locations of objects after locomoting to a new position is no more difficult than doing so from the original standpoint (Rieser, 1989; Rieser et al., 1986). However, difficulties arise when judgments are made from perspectives that are imagined (Presson & Montello, 1994). For example, Rieser has shown that pointing to objects from a novel standpoint is slower and less accurate when the observer mentally rotates to the new standpoint than when she is physically rotated to it.

In short, the evidence suggests that moving organisms update their representations of their surroundings in an efficient and effortless manner. However, non-moving organisms need to engage in additional mental processing in order to reason about their surroundings from imagined standpoints.

The majority of the previous studies have examined spatial updating with paradigms that involved visually presented stimuli. Visual perception is not, however, the only way we form mental representations of the world. Very often, we learn about space by reading or listening to verbal descriptions. A number of studies (e.g., Denis & Cocude, 1989) have shown that at least in terms of geometrical properties, mental representations constructed from language are equivalent to those created through perception. In general, mental representations of space seem to preserve many of the characteristics of real environments (Zwaan & Radvansky, 1998).

An interesting issue that arises is whether mental representations derived from text are updated when changes in the spatial relations come about. A study by De Vega and Rodrigo (2001) attempted to provide an answer to this question by contrasting how easily people locate objects after physical and imagined rotations. In that study, participants first read sentences that described spatial layouts in which objects were located at each of the four canonical horizontal directions from a protagonist. The protagonist was then described to rotate to novel perspectives. The subjects were probed with the names of the objects and were asked to determine their locations from the perspective of the protagonist. One group of participants performed the task by physically rotating along with the protagonist, while a different group performed the task with no physical rotation. De Vega and Rodrigo contrasted the judgment latencies of the two groups to assess whether spatial updating took place. In one experiment that required that subjects use spatial labels (i.e., front, left etc) to provide their answers, performance was equally fast for the two rotation modes. In another experiment in which subjects pointed to objects, performance was faster when rotation was physical instead of imagined. De Vega and Rodrigo concluded that physical rotations led to effortless updating only in the pointing experiment. Furthermore, they suggested that the actual body position of the participant is not important for performing the task when responses are made by using spatial labels. That is because subjects performed the task in a represented framework from which their actual self was disengaged.

Certain limitations of the study by De Vega and Rodrigo (2001) create concerns regarding the

interpretation of the results. First, the absence of a difference between physical and imagined rotation latencies in the labeling task does not necessarily mean that participants failed to effortlessly update their representations. It could very well be the case that they were successful at updating their representations under both modes of rotation. This is quite possible given the simplicity of the scene and its relatively low working memory demands (only four objects needed to be tracked). Second, although no differences were observed in the latency measures, subjects were significantly more accurate in their judgments with physical rotations than with imagined rotations.

The present study uses a different measure to examine whether spatial updating takes place under either imagined or physical rotations. Performance under the original perspective (i.e. the perspective from which the scene is encoded) and novel perspectives is contrasted in the two modes of rotation. If subjects fail to update their original representation when they rotate – either physically or imaginary – to a novel orientation, then performance should be better when the task is performed from the original than from the novel perspectives. If any of the two modes of rotation results in successful updating, this should be indicated by equal performance between the original and novel perspectives.

A second goal of the study is to examine more closely the role – if any – of the participants' ecological frame in tasks that require judgments using deictic terms. A hypothesis of the present study is that the orientation of ecological frame affects how easily people discriminate the two poles of an axis and map spatial terms to the appropriate regions of space. If this is true then the orientation of the participants' bodies will affect the ease of using deictic terms in the task. This should be particularly true for judgments within the left/right axis because our bodies provide the only source of asymmetry for this axis. Manual dexterity is probably the least subtle cue that people can use to discriminate left from right (Corballis & Beale, 1976). Therefore, the prediction is that left Vs right judgments will be less difficult when the ecological reference frame of the participant is aligned with the reference frame imposed on the protagonist.

Experimental Task

The present study uses a paradigm that has been used widely in the past to study the accessibility of directions in spatial memory. The task, developed by Franklin and Tversky (1990), involves the presentation of a narrative which describes a naturalistic scene in the second person. Objects are described occupying positions at canonical directions from the protagonist (i.e., above, in the front, on the left etc). Participants are given unlimited time to study the narrative. Then, the

protagonist is described to rotate to a new orientation. The narrative continues on a sentence by sentence fashion with participants pressing a key to request a new sentence. Occasionally, instead of a new sentence, the name of an object appears. Participants are asked to report where the object is with respect to the current perspective of the protagonist. The task continues until all objects are probed from various perspectives.

Studies that used this paradigm (e.g., Bryant & Tversky, 1992) were primarily focused on the accessibility pattern for the various self-object directions. Therefore, latencies from the various protagonist perspectives were collapsed to provide a single average value for each direction. The major result from these studies is that objects on the above/below axis are located faster than objects on the front/back axis, which are in turn located faster than objects on the left/right axis. Furthermore, objects in the front are retrieved faster than objects at the back of the protagonist. An account for this accessibility pattern has been provided by the Spatial Frameworks model (Franklin & Tversky, 1990) which posits that the scene is represented on the basis of the three orthogonal body axes.

The current study uses the Spatial Frameworks paradigm to examine latency differences – if any – between the original and the novel perspectives of the protagonist. As in De Vega and Rodrigo (2001), a mode of rotation manipulation is introduced. A group of participants perform the task by physically rotating to novel perspectives while a different group of participants perform the task by only imagining rotations to novel perspectives. In contrast to the narratives of De Vega and Rodrigo, the present study involves narratives that are somewhat more complex. In addition to the four objects in the horizontal plane, another two objects are described to occupy the poles of the above/below axis. Because all protagonist reorientations occur in the horizontal plane, the positions of these two objects do not need to be updated at all throughout the task. Nevertheless, they add an extra load on working memory, thus making the task more cognitively demanding.

In order to examine the role of the ecological frame, another variable is introduced. Half of the narratives require that subjects respond with a direction judgment (e.g., left, front etc) while in the other half they simply need to respond with an axis judgment. In the latter case, if for example the object is located on the left of the protagonist, the participant only need to respond with "left/right". This manipulation has been previously used with this paradigm in a study by Bryant and Wright (1999). The rationale for including the judgment type manipulation in the present study is that if the ecological reference frame helps to make easier direction judgments, then simply removing the need for such judgments will produce the same effect. Furthermore, if real rotations and axis judgments affect

performance in the same way, then having one of them should be sufficient; that is, no better performance will be observed when both of them apply instead of just one.

Method

Participants Forty students (20 females) from psychology classes at the Pennsylvania State University participated in the experiment in exchange for course credit. Ten male and 10 female participants were randomly assigned to the physical and the imagined rotation conditions.

Materials Four narratives, taken from those used by Franklin and Tversky (1990) and two taken from Bryant & Wright (1999) were used in the present study. The first portion of the narratives described in the second person a naturalistic scene -- a barn, a construction site, a hotel lobby, a space museum, a lagoon, and a navy ship -- in which objects were located at the six canonical axes of the reader-protagonist. Narratives were modified to include 6 instead of 5 objects and in contrast with Franklin and Tversky, the initial portions were also presented on computers. The six critical objects in each narrative appeared in blue upper-case characters, in contrast to the rest of the narrative which appeared in lower-case black characters. The order in which objects were introduced in the initial portions of the narratives was determined with the use of a 6 x 6 Latin Square so that each object direction appeared at a different serial position in each narrative. For each participant, half of the narratives were randomly assigned to the direction judgment condition and the other half to the axis judgment condition. Narratives were presented to participants in a random order with the constraint that no more than 2 narratives of the same judgment type were presented in sequence.

Design The experiment was a 2 (mode of rotation: imagined, real) x 2 (type of judgment: direction, axis) x 2 (perspective: original, novel) x 6 (self-object directions: above, below, front, back, left, right) mixed factorial design. The type of rotation was manipulated between subjects while both the type of judgment and self-object directions varied within subjects. Each self-object direction was tested four times in each narrative, once under each of the four possible perspectives. Self-object directions were tested in a random order within each perspective. Also, the original perspective was never the first perspective that subjects were tested on.

Procedure The procedure was similar to the one used by Franklin and Tversky (1990). Two main differences from De Vega and Rodrigo (2001) were that a voice key was not used to collect responses and that the narratives included objects located on the above/below axis. The narratives were presented on a laptop

computer that participants held onto their laps while sitting in a swivel chair. Participants were given unlimited time to study the first portion of the narratives. The narrative then continued in a sentence by sentence fashion with subjects pressing the space bar to request a new sentence. The second sentence after the first portion described the protagonist rotating to a new orientation in the horizontal plane. Depending on the condition they were assigned to, participants were instructed to either turn their selves by swiveling the chair to produce the reorientations that were described in the text, or to imagine their selves rotating without changing their actual orientation at any point throughout the experiment. After two filler sentences were presented, the name of one of the objects in the scene appeared. Subjects were instructed to press the space bar as soon as they were ready to report the relative position of the object. The time between the appearance of the object probe and the space bar press was the critical latency measure and will hereinafter be referred to as *response latency*. For direction judgments, when subjects pressed the space bar, a list with the terms "above", "below", "front", "back", "left", and "right", presented in a random order each time, appeared. Participants were instructed to press the key that corresponded to the integer (1 to 6) that appeared next to the direction they chose. For axis judgments, the list contained the choices "above/below", "front/back", and "left/right", and participants entered their answer using the 1 to 3 keys. The time between the appearance of the list and the key press for selecting the direction will be referred to as *answer latency*. Each narrative continued in the same fashion until all six objects were probed in each protagonist perspective. Each narrative involved 24 probes, 6 for each protagonist perspective. For each participant, three of the narratives were randomly assigned to the direction judgment type, and the rest to the axis judgment type. Below each object probe the words "direction" or "axis" were presented to remind participants of the type of response they needed to make.

Results

Participants responded correctly to 96.3% of the probes. Data from 2 subjects -- one from each rotation condition -- were discarded because accuracy did not exceed 60%.

Latency Incorrect responses were discarded from the latency analyses. Outliers in latency data were defined as reaction times deviating more than 3 standard deviations from each participant's type of judgment mean. Outliers in response RT resulted in an additional 6% of data and were also discarded from the analyses. Latency data for each self-object direction were collapsed to form three dimension means (i.e., a

separate mean of each body axis). Moreover, latencies for the three novel perspectives did not differ from each other so they were collapsed to form a single novel perspective mean.

Answer Latency Analyzing answer RT provides a check on whether subjects successfully followed instructions on how to respond. Frequently, spillover effects of response RT on answer RT are observed. When this happens, however, answer RT patterns tend to mimic the ones observed in the response RT data and are either omitted from analyses (e.g., Bryant, Tversky, & Franklin, 1992) or combined with response RT (Franklin, Tversky, & Coon, 1992). No spill-over effects were observed in the present study. The only significant effect was a main effect for the type of judgment, $F(1,36)=90.28$, $MSE=105394$, $p<.001$. The average answer RT for direction judgments was greater than the corresponding RT for axis judgments (1944 ms and 1655 ms respectively). This is expected because the response choices were 3 for axis judgments and 6 for direction judgments.

Response Latency Several Analyses of Variance (ANOVA's) were performed. Interactions that are not discussed were not significant at $\alpha=.05$.

As predicted, a significant mode of rotation x perspective x dimension interaction was obtained, $F(2,72)=4.23$, $MSE=75530$, $p<.05$ (figure 1).

Separate ANOVAS were performed for each mode of rotation.

When rotation was imagined, a significant perspective x dimension interaction was obtained, $F(2,36)=8.05$, $MSE=114939$, $p<.01$. Significant main effects for both perspective and dimension were obtained, $F(1,18)=22.93$, $MSE=264189$, $p<.001$ and $F(2,36)=19.57$, $MSE=212008$, $p<.001$ respectively. Performance was faster with the original than the novel perspective for above/below and left/right. For front/back the difference was not statistically significant, $F(1,18)=2.73$, $MSE=193450$, $p=.12$. Nevertheless, even in this dimension the average for the original perspective was smaller than that for novel perspective (2127 ms and 2363 ms respectively). Overall, the patterns of accessibility of the three axes conformed to the predictions of the Spatial Frameworks model for both the original and novel perspectives. Judgments on the left/right dimension were particularly slow when performed under a novel perspective (3025 ms) than under the original perspective (2208 ms), $F(1,18)=32.83$, $MSE=193290$, $p<.001$.

When rotation was physical, latency for the original perspective was shorter than the average latency for the novel perspective (1821 ms and 2149 ms respectively), $F(1,18)=57.26$, $MSE=53699$, $p<.001$. The perspective x dimension interaction was not significant, $F(2,36)=1.99$, $MSE=36120$, $p=.15$. However, there was a main effect of dimension, $F(2,36)=21.61$,

$MSE=55533$, $p<.001$. The pattern of latencies for the three body axes corresponded with the pattern predicted by the Spatial Frameworks model.

Figure 1: Latency for body axes as a function of the mode of rotation and the perspective of the protagonist.

Additionally, the analysis revealed a mode of rotation x judgment type x dimension interaction, $F(2,70)=3.49$, $MSE=60334$, $p<.05$.

Figure 2: Latency for body axes as a function of the mode of rotation and the judgment type.

Further analyses were performed separately for each judgment type. When judgment was direction, a significant rotation x dimension interaction was obtained, $F(2,72)=6.61$, $MSE=134329$, $p<.01$. Overall with direction judgments, subjects were faster when the rotation was physical than imagined (2507 ms and 1979 ms respectively), $F(1,36)=5.48$, $MSE=1448481$, $p<.05$. An effect for dimension was also present, $F(2,72)=31.49$, $MSE=134329$, $p<.001$. Latency patterns conformed to the Spatial Frameworks model for both rotation modes. However, times were longer for all dimensions when rotation was imagined. The interaction was caused by a very long latency average for the left/right dimension under imagined rotations. When the judgment was axis, latencies for the various axes were similar for both types of rotation. The rotation x dimension interaction did not approach significance, $F(2,7)=1.23$, $MSE=84641$, $p=.30$. Similarly, no main effect for rotation mode was obtained, $F(1,35)=.07$, $MSE=1353673$, $p=.80$. However, a significant main effect for dimension was

obtained, $F(2,70)=30.96$, $MSE=84641$, $p<.001$. The Spatial Frameworks pattern was observed in the dimension latencies. As seen in figure 2, the average latency for the left/right dimension (2452 ms) was shorter than the respective average of imagined rotation with a direction decision (3045 ms) but longer than that of real rotation with a direction decision (2170 ms).

An interesting result was the pattern observed for the rotation x judgment interaction, $F(1,35)=11.66$, $MSE=216901$, $p<.01$. When rotation was imagined, axis judgments (2212 ms) were faster than directional judgments (2463 ms), $F(1,17)=8$, $MSE=212424$, $p<.05$. However, when rotation was physical, the pattern of judgment times were actually opposite than the one obtained with imagined rotations. Axis judgments took longer than direction judgments (2155ms and 1979ms respectively). This difference was marginally significant, $F(1,18)=4$, $MSE=221130$, $p=.06$. A further analysis revealed that a significant type of judgment x perspective interaction for imagined rotations, $F(1,17)=5$, $MSE=24966$, $p<.05$. For novel perspective, direction judgments were performed significantly faster than axis judgments, $F(1,17)=13.6$, $MSE=56705$, $p<.01$. However, for the original perspective the two judgment types were not statistically different, $F(1,17)=0.95$, $MSE=150568$, $p=.34$.

Accuracy In contrast to the latency analysis, the ANOVA on accuracy revealed a significant main effect for the mode of rotation, $F(1,36)=4.41$, $MSE=.017$, $p<.05$. Accuracy was higher when rotations were physical instead of imagined (98% and 94% respectively). An advantage for physical rotation is also reported by De Vega and Rodrigo (2001). A significant mode of rotation x type of judgment interaction, $F(1,36)=5.32$, $MSE=.017$, $p<.05$, revealed that the effect of rotation was confined to direction judgments.

As in the latency analysis, a significant mode of rotation x perspective x dimension interaction was obtained, $F(2,72)=3.84$, $MSE=.0008$, $p<.05$. The mode of rotation x judgment x dimension interaction that was obtained in the latency analysis, was marginally significant, $F(2,72)=3.07$, $MSE=.002$, $p=.05$. For both interactions, the pattern of results resembled the patterns obtained in the latency analysis to a great extent. The only deviation from the latency data was that sometimes the judgments for front/back were no less accurate than judgments for above/below.

Discussion

The present experiment produced results that deviated from those reported by De Vega and Rodrigo (2001). When participants made direction judgments – the condition tested by De Vega and Rodrigo – they were both faster and more accurate with physical than imagined rotations. De Vega and Rodrigo reported that

their subjects were more accurate but not faster with physical rotations. Perhaps, the use of only four objects in their narratives made it easy for participants to keep track of how their relative locations of objects changed with the protagonist reorientations.

Although the performance advantage for physical rotation would qualify as evidence for successful updating under De Vega and Rodrigo's (2001) methodology, other results from the present study suggest otherwise. Results suggest that the fastest performance under physical rotations was due to the relative ease with which direction judgments, especially left Vs right, were made when rotation was physical. The same result was obtained for imagined rotation when axis judgments were introduced. Indeed, when participants were not required to make a direction judgment, their performance was similar to that of participants with physical rotations. This suggests that the orientation of the ecological reference frame is important for making difficult discriminations between the poles of body-centric axes. The differences between the three dimensions were smaller when the ecological frame was aligned with the frame of the protagonist. This was true both when participants performed the task from the original perspective, under which their ecological frame is aligned with the protagonist frame, in either mode of rotation.

Despite the performance advantage with physical rotations, the present results provide clear evidence that participants did not update the self-object direction with either imagined nor physical rotations. In both cases, performance was both faster and more accurate when the task was performed from the original than a novel perspective. This result is not obtained in studies that use visually presented scenes (e.g., Rieser et al., 1986), and suggests one aspect that mental representations derived from texts might differ from those derived from perception. A possible account for this dissociation is provided by De Vega and Rodrigo (2001). While visually perceived scenes are anchored in a sensorimotor framework based on the ecological reference frame of the observer, mental representations of described scenes are grounded into a mental framework from which the self is detached. While physical movements can provide proprioceptive feedback that helps updating the mental representation in the sensorimotor framework, this feedback is not very helpful for representations that are anchored in a mental framework. However, as shown in the present study, although the ecological self might be disengaged from the mental framework, it is still important for making spatial decisions in it.

Finally, the accessibility patterns for the three dimensions conformed to the predictions of the Spatial Frameworks model (Franklin & Tversky, 1990). Objects on the above/below axis were located faster

than objects on the front/back axis, which were in turn located faster than objects on the left/right axis. The differences among the dimensions were greater when rotations were imagined and judgments were for direction. While this result might be due to the higher difficulty of performing the task under these circumstances, it could alternatively mean that a part of the Spatial Frameworks effect is due to the need for discriminating the poles of the axes. Results from Bryant and Wright (1999) suggest that the difficulty of making discriminating decisions within the axes does not fully account for the Spatial Frameworks results.

In summary, the present study provided more substantial evidence to confirm the conclusions of De Vega and Rodrigo (2001), while at the same time provided a better understanding of how the ecological self interacts with spatial reasoning about imagined spaces derived from texts. While physical rotations led to no spatial updating of the original mental representation, they produced better performance by reducing the difficulty with making discrimination between the poles of body-centric axes. This result can have important practical implications for situations where spatial reasoning occurs from imagined perspectives (e.g., teleoperating robots for rescue mission and space exploration).

Acknowledgments

I am grateful to Barbara Tversky for providing narrative material and Jessica Glick for modifying that material for use in the present study. For valuable discussions, I thank Rich Carlson, Frank Ritter, Judy Kroll, and Lael Schooler. I also thank Allison DeGrano, Tom Jolly, and Jessica Glick for their enthusiastic help with data collection.

Abstract

Despite the postulated importance of analogising to human cognition, the study of analogical problem solving in the laboratory has found disappointing results. Providing an analogue to a participant prior to asking them to solve a problem gives only a small benefit at best. Recently, studies outside the laboratory have suggested that experts frequently use analogies in real-world situations. It is less clear whether novices can also spontaneously invoke and use analogies to solve realistic problems. In the current investigation, undergraduates were observed solving a large-scale management problem over two weeks. It was found that many analogies were produced (on average 4.6 per one-hour session), and that 77% of these analogies reflected a structural rather than a superficial mapping between a base and a target. It was also determined that 56% of these structural analogies involved non-trivial mappings of higher-order relations. Further, it was found that analogies were drawn to serve two different purposes: problem solving and illustration. In generating illustrative analogies, participants frequently made superficial mappings, but when generating analogies to solve problems, they never made purely superficial mappings.

Analogy is defined by the Oxford English Dictionary as the "resemblance of relations or attributes as a ground of reasoning." The ability to draw analogies is considered to be fundamental to intelligent human behaviour (Holyoak & Thagard, 1995). Analogy appears to be central to both the processing of information and its retrieval from long-term memory (Shank, 1999) and underpins theories of creative thinking and intelligence (Holyoak & Thagard, 1995; Poze, 1983; Raven, 1938; Sternberg, 1977).

The postulated importance of analogising for intelligent human behaviour stands in contrast to the findings from laboratory studies of analogical problem solving. It is often found that providing a superficially dissimilar but structurally analogous source to a

participant prior to them solving a target problem, without a hint about either its relevance or relatedness to the target, gives little or no gain in target solution rates (Anoli, Antonietti, Crisafulli & Cantoia, 2001; Gick & Holyoak, 1980, 1983).

Transfer of the analogous solution without a hint is not improved by: providing a static diagrammatic representation of the structural analogue (Gick & Holyoak, 1983; Podone, Hummel & Holyoak, 2001); providing an abstract verbal statement of the underlying structural analogue (Gick & Holyoak, 1983); or simply re-presenting the source to the participant while they are processing the target (Anoli et al., 2001; Gick & Holyoak, 1980). There is some evidence of analogical transfer when multiple analogous sources are provided (Catrambone & Holyoak, 1989; Gick & Holyoak, 1983), and also when the analogous source is a general concept (Schunn & Dunbar, 1996). Generally, however, the findings from laboratory-based studies of analogy have been disappointing.

Recently, analogy has begun to be investigated in applied as well as experimental contexts. This research has particularly focused on the behaviour of experts. For example, Hargadon (1999) describes how 'knowledge brokers' in management draw comparisons between different areas in order to move ideas from where they are known to where they are not. Marchant, Robinson, Anderson and Schadewald (1993) investigated the use of analogies in the interpretation of tax statutes in graduate students and professional lawyers. They found that both groups demonstrated high rates of transfer from a structural analogue. Dunbar and Blanchette (2001; Dunbar, 2001) have documented the use of analogy by immunologists and molecular biologists, finding that structural analogising was particularly prevalent when the scientist was engaged in theory building. Dunbar and Blanchette (2001) were also able to determine the function of the analogies in their observations. When *isolated*

unexpected results occurred the scientists drew analogies to similar experiments, what Dunbar and Blanchette (2001) call local analogies. However, when a *series* of unexpected results occurred the scientists drew more distant analogies to the function of similar components in other organisms. The type of mapping appears to differ depending on the purpose for which it is drawn.

Thus, it appears that experts in applied settings are able to draw analogies between base and target problems. This is consistent with the widely held view that differences between experts and novices reflect different representational levels of information encoding. Experts are able to encode information at a deeper, structural level, while novices generally only encode information at a surface or superficial level (Chi, Feltovich & Glaser, 1981; Klein, 1999; Novick, 1988). Consistent with this explanation is a study by Thompson, Gentner and Loewenstein (2000), which found that unless management students were actively encouraged to compare source analogues in order to draw out structural relations, then rates of transfer of an underlying concept were low.

There is some evidence, however, that novices can also make use of structural analogies without being encouraged to create structural mappings. Blanchette and Dunbar (2000, 2001; Dunbar, 2001) found that novices were able to draw structural inferences when reasoning using metaphors. In a study where participants had to *explain* a concept to another person using a metaphor, it was found that the metaphor was frequently chosen from a domain outside the one being explained, suggesting that cross-structural mapping was occurring. One of the important aspects of Blanchette and Dunbar's study may be that participants were able to draw on any area of their knowledge in creating the analogies. This is in contrast to the previous studies involving novices that have examined the ability to produce a specific analogical mapping. Thus, it may be that novices are able to use analogy effectively if they are allowed to draw on memory more generally.

Metaphors are, however, slightly different from the types of analogies drawn to *solve* problems. Although metaphor relies upon the mechanism of analogy it is different from the kinds of analogy used in problem solving in two key respects. First, the relationship between source and target is different. In using analogy to solve problems the person must find a source that informs a less well understood target, whilst in drawing a metaphor a person has a target and must generate a source that explicates the underlying topic (Holyoak & Thagard, 1995). Second, metaphors often depend upon a combination with metonymy (where ideas substitute for each other) and the pattern of relations often shifts because of this in a way that problem solving analogies rarely do (Holyoak & Thagard, 1995).

The present study was, therefore, designed to extend existing research by addressing the question of whether novices can spontaneously make analogical mappings in order to solve management problems if they are allowed to draw more widely on stored knowledge. Also, in light of Blanchette and Dunbar's (2001) observations concerning the differing functions of analogies in real-world situations, we were alert to the possibility that management contexts might similarly be associated with analogy use aimed at achieving different functions.

Method

The study investigated undergraduate students in Management conducting an analysis of a 'business case' as part of a 'case method' course, a teaching method designed to simulate real-life management decision-making (Easton, 1992). Participants worked in groups and were required to specify the problems and opportunities inherent in the case, and to produce a set of solutions that might optimise the business described in the case. The task may be described as ill-defined (Van Lehn, 1989) and in some respects, un-defined. No restrictions were placed on the knowledge sources that participants might employ during the case analysis. No source analogues were presented to participants, and the concept of analogy was not mentioned to them as part of the course or the investigation.

Materials

The cases consisted of descriptions of a business or industry facing a loosely defined threat or opportunity. The business cases were chosen for their pedagogical merit by the assessing tutor and consisted of three different situations that described the position of a business or industry. The cases were 'The Champagne Industry in 1993' (Cool, Howe & Henderson, 1994), 'Petrol Retailing in Europe: The UK Market' (Levy, 1999), and 'Delta Dairies' (Easton & Dritsas, 1992). The cases were 19, 13 and 11 pages long, respectively, and are available from the European Case Clearing House Collection (<http://www.ecch.cranfield.ac.uk>).

Participants

The participants were 24 final year undergraduate students from Lancaster University. The outcomes of each group's analysis was examined by a tutor as part of the student's course assessment. Participants were not paid.

Procedure

Six groups of four people were formed on the basis of who would and wouldn't work well with each other by the assessing tutor. Each group examined a single case with each case being analysed twice by two separate

groups. The groups spent two weeks conducting an analysis of their case. During this period the groups met both on their own and with the tutor. The groups met with the tutor between three and four times for approximately an hour. It is data from these sessions that were used for the present investigation. At the end of the analysis period the groups were required to make a 20 minute presentation to their peers, in the form of recommendations for the business.

Results

19 tutorials (out of a possible 22) were observed and audio-taped. Instances of analogising in the tutorials were transcribed from the audio-tapes (off-task analogies were excluded). For the purposes of this study, analogy was considered to have occurred when reference was made to an episode of prior experience (a base) and was applied to a current idea in some way (a target). The extract was excluded when the base was drawn from lectures, the assessing tutor or directly from the case. The application of management knowledge or general knowledge was not considered to be an analogy in this study. A 15% sample of these tapes was re-coded by a second coder, and any discrepancies in analogy extraction were discussed until consensus was reached. Over the 19 tutorials there were 86 occasions when an analogy was made, a mean of 4.5 analogies per hour-long tutorial (standard deviation = 4.98, range = 0-20) and only one tutorial contained no discernible analogising.

Structure of the Analogies

The extracts of analogies were sorted into three categories based on a form of predicate calculus similar to that used by Gentner (1983). Extracts were defined in terms of whether the mapping between the base and the target involved merely superficial attributes, a first-order relation, or a complex systemic relation. An extract was classed as superficial if the mapping was in terms of objects only, with no discernible structural mapping. A simple, first-order relational mapping occurred when a simple relation that held in the source was also observed to hold in the target. A complex mapping of systems of relations occurred when higher-order relations were seen to be mapped, such as causal relations or plot structure (cf. Gentner, 1983).

It was found that 43% of the analogies generated that included an explicit mention of a target and base situation involved mappings of higher-order relations, such as can be seen in the following extract:

P1: "The marketing option, as well, which we'll use on the short-term; have you seen the BP advert?"

CL: Yes.

P1: We're going down that line. We were saying so the other day. The amount at which it burns cleaner is negligible, but perceptions - so go for a cleaner image in the way BP are doing now. They're playing on the fact that that pollution is becoming more and more evident. Everybody is starting to understand it now, accept it, rather than just saying, 'it's rubbish that, we're not Greenpeace people'. It's becoming more of a factor in society against dirty polluting petrol. So, I mean, using the BP model, try to change people's perceptions about what your company at the moment, what the fuel is in [inaudible] it a greener alternative." [Group 4, 2nd tutorial]

The analogical mapping from base and target that is apparent in this extract can be restated using a propositional formalism, as follows:

Cause [Cause [Becoming-more-evident(Pollution), Becoming-greener(Society)], Use-as-marketing-option (BP, Green-standpoint)] ↔ Cause [Cause [Becoming-more-evident(Pollution), Becoming-greener(Society)], Use-as-marketing-option (Company-Y, Green-standpoint)]

The initial set of propositions capture the idea that the company in the base situation (British Petroleum) is taking a green standpoint because society is becoming greener in response to pollution becoming more evident. It is these systems of causal relations that this management group is mapping across to their own marketing option. It is noteworthy, too, that there are a number of higher-order relationships evident in the base situation, and the fact that these relations get mapped between base and target appears to demonstrate that novices can produce non-trivial analogies with sophisticated relational structures.

A further 34% of the analogies that involved the explicit mention of base and target situations involved first-order relational mappings. An example of such a mapping can be observed in the following extract:

P1: "That does happen though doesn't it, in supermarkets?"

CL: What?

P1: That you could, it goes both - the exclusivity goes both ways but for huge brands, not the same size as ours. They state that a competitor can't be (sold in the supermarket)." [Group 2, 3rd tutorial]

This analogy can be represented propositionally as:

Has-exclusivity-deal-with(Huge-brand, Supermarket) ↔ Has-exclusivity-deal-with(Company-Y, Supermarket)

Here the group is thinking of copying the idea that they think is used by big companies of forcing a competitor off the shelves of a supermarket by signing an exclusivity deal.

Overall, then, 77% of the analogies produced by the novices observed in this study were based on structural mappings (either first-order relations or higher-order relations).

Function of the Analogies

The data were subjected to a thematic analysis in order to investigate further the type and function of the analogies employed by the management novices in this study. The emphasis in this analysis was on the *solution* or *idea* that emerged from the mapping, rather than on the nature of the mapping itself. In a thematic analysis extracts are grouped together based on their similarity, such that categories are developed based on common themes. Thematic analysis is a useful way of sorting qualitative data so that categories are allowed to emerge in a relatively atheoretical way (see Plummer, 1995; Smith, 1995). A second coder was able to recreate the themes identified with 88% accuracy (following a training session using 1/3 of the data). This analysis indicated that analogies were appearing to serve two different functions: problem solving and illustration.

Problem-Solving Analogies Of these analogies, 23% were direct base-to-target solutions, with both base and target present in the same extract. These took the form of 'x did y, so we can copy them'. For example:

"You could go on convenience a bit because there is an Esso station in Southampton, where I'm from, that is totally self-sufficient. It doesn't have anybody working there, and has, like, Coke dispensers, and all the kinds of food dispensers, and you pay at the pump and then you, you know, I've seen people pick up snacks from these machines and then they go. They're completely unmanned. That might be a possibility for convenience." [Group 3, 1st tutorial]

This type of analogy may be represented propositionally as:

Market-on-convenience(Esso-station,Fully-self-service)

↔

Market-on-convenience(Company-Y,Fully-self-service)

A further 15% of the analogies were elaborated base-to-target solutions. In these cases, a base was mapped to the target as in the direct base-to-target solutions, but the information gained from the analogy was used to form a new solution, rather than simply mapping the solution across wholesale from the base. For example:

"Another thing that we were having difficulty coming up with is an actual price, because we were thinking, 'Shall we out-price Moet et Chandon by only a small amount because it gives that exclusivity, and we didn't want to go for exactly the same price because we've got this unique selling point?' So if you just did it a tiny bit more expensive, going to that bit much it's as good as and it's got this unique selling point, and it's only a tiny bit more so that it's not too much of a stretch to buy it over Moet et Chandon. So people realise that it must be better, because it's that bit more expensive, and it's got this unique selling point." [Group 2, 2nd tutorial].

This analogy and its associated solution development may be represented in propositional form as:

Analogy: Use-as-marketing-points (Moet-et-Chandon, Product-quality-and-product-exclusivity) and Indexed-by (Product-quality, High-price) ↔

Use-as-marketing-points (Company-Y, Product-quality-and-product-exclusivity) and Indexed-by (Product-quality, High-price)

Solution idea: Cause [More-expensive-than (Company-Y-one-press-champagne, Moet-et-Chandon-champagne), Gain-market-advantage-over (Company-Y, Moet-et-Chandon)]

An additional 35% of the analogies were sources that shaped the group's decision making but which lacked a target that was explicitly referenced in the extract itself. An example of this comes from Group 2, 2nd tutorial:

"You know, like, how Safeway have got a grading system where, like, they've got bronze, silver and gold labelled wines, and things like that, you know, if they have something, I don't know what Casino have. But the supermarket's recommendation can be quite powerful. If you're looking for a wine in Safeway's and you don't particularly recognise the label, if you read the little Safeway bit on the back you know it's this level of sweetness, and it goes with this and that and the other. You're quite tempted to try some first time."

This extract shows that the group has taken the idea of the power of the supermarket's recommendation and this later guides the group's solution towards striking a deal with a French supermarket which leads to the recommendation of a dual-branding scheme, where the supermarket and the producer's name is on the bottle.

All of the analogies produced in order to serve a problem-solving purpose used either higher-order relational mappings or first-order relational mappings. There were no purely superficial mappings used to solve a problem.

Illustrative Analogies Twenty-seven percent of the analogies were designed not to facilitate directly the generation of a new solution idea, but instead for the purpose of exemplifying or illustrating an existing idea. Such analogies, therefore, appeared to be metaphorical in nature and intent rather than directed at problem solving *per se*. In such cases, the participant generated a source to explicate the target. For example, a member of Group 4 (2nd tutorial) drew parallels between the market positions of Coca Cola and Pepsi to illustrate the position faced by an oil company under consideration:

"You know, you said the other day that Coca Cola and Pepsi are within an arm's reach, - there's not much of a differentiation. It's the same here. It's just we've got more petrol stations and more people buying out of convenience."

The previous extracts concerned global target ideas of facilitating convenience at petrol stations, and the pricing for a new one-press champagne. In contrast, the illustration analogies lack these overarching ideas and extend no further than the base to target mapping. They are merely designed as a comparison of one idea with another.

In contrast to the analogies drawn to solve problems where there was no superficial mappings, when the analogy was drawn for illustrative purposes, 57% of the analogies were based on superficial mappings (with 26% based on higher-order mappings and 17% based on first-order relations).

When participants are solving problems it does not make any sense to map a superficially similar but structurally dissimilar source to a target, since this would not aid problem solving. In contrast, when an analogy is merely being used for illustrative purposes, it is possible simply to use a superficial mapping, since the purpose is merely to facilitate understanding rather than advance solution development.

Discussion

These results are important for two main reasons. First, by demonstrating spontaneous analogising by novice problem-solvers in a naturalistic domain, they corroborate the widely held view (e.g., Anderson, 2000; Holland, Holyoak, Nisbett & Thagard, 1986) that analogising plays a fundamental role in human problem-solving. Second, the emphasis on structural rather than superficial mappings demonstrates a sophistication in the manipulation of domain knowledge that is not usually associated with novices. It may be that, in some domains at least, novices are quite capable of recognising and manipulating information at a conceptual rather than superficial level.

Like the experts observed by Dunbar and Blanchette (2000), it was observed in this study that novices also drew analogies to serve different purposes, and that the nature of the mapping differs depending on this purpose. When solving problems, the novices used only first-order and higher-order relational mappings. However, when they were illustrating an idea, over half of the analogies were made using superficial mappings.

The analysis also highlighted a potentially important distinction between solutions that are simply *mapped across* from a source analogue, and solutions that are developed as a result of additional idea generation subsequent to the attainment of an analogical mapping. It may be that much of the skill in management problem solving is to extend and elaborate upon initial analogical mappings.

There are some important qualifications to our results. Perhaps the key one is that the data we report here reflect group tutorial activity in which a fair proportion of the exchanges consist of the communication of ideas and outcomes among participants. On the basis of these data alone, we cannot ascertain whether the role played by analogy is one of genuine problem-solving, or whether it serves a mainly communicative role, making ideas and solutions that have been discovered and worked through using other problem-solving strategies easier to share between individuals. In a sense, it does not affect the outcomes reported here, since either role is crucial in collaborative problem-solving. However, future studies that are not tutorial-based are needed to determine the precise function of novice analogising in this domain.

This investigation differs from experimental studies of analogy in the following key ways. First, analogies could be drawn from any area of a participant's experience, and sources were not provided by the experimenter. Second, participants solved the problems in groups rather than individually. Third, the participants had two weeks of discussion-based learning to analyse and solve the presented problem. It is clear that the method of exploring analogy use employed here and the standard experimental method represent very different paradigms, such that direct comparisons between the two should be drawn with caution. However, considering that experiments are supposed to be analogues of real-world situations in a simplified form, a reconsideration as to how analogical problem solving can fruitfully be investigated experimentally may need to be undertaken in light of the mounting evidence that people frequently make cross-structural analogies in the real-world.

Acknowledgements

This research was funded by an ESRC grant to the first and third authors, with co-funding from the European Case Clearing House. We are grateful to Geoff Easton

for providing us with access to his students, and to Rosamund Ward who acted as the second coder for our coding-reliability checks.

Neonatal Learning of Faces: Environmental and Genetic Influences

James A. Bednar (jbednar@cs.utexas.edu)

Risto Miikkulainen (risto@cs.utexas.edu)

Department of Computer Sciences, The University of Texas at Austin
Austin, TX 78712 USA

Abstract

Newborn face perception is controversial, but the current evidence suggests that (a) newborns follow face-like schematic patterns further than similar patterns, (b) infants can learn individual faces soon after birth, and (c) full face processing abilities develop through months or years of experience with faces. Previous models have not adequately accounted for all three types of results. In prior work, we showed how a biologically based self-organizing system and spontaneous activity patterns can explain newborn face preferences. In this paper we show that this general-purpose learning system can explain both neonatal and later learning. Using computational simulations, we demonstrate that newborn learning need not be based on the external outline, as has been supposed, and that postnatal decreases in response to schematic faces need not represent a decrease in response to real faces. These simulations provide concrete predictions to guide future experiments with infants, while suggesting new techniques for designing complex adaptive systems in general.

Introduction

Specific regions in the adult visual cortex respond preferentially to human faces. How this face processing capability develops is not yet clear. Many researchers have argued that infants process only general visual properties like size and spatial frequency until after weeks or months of experience (Maurer & Barrera, 1981). Others have found a preference for faces at birth (Goren, Sarty, & Wu, 1975; Johnson, Dziurawiec, Ellis, & Morton, 1991; Simion, Valenza, & Umiltà, 1998) and that infants can learn and discriminate between specific faces even in the first few hours and days after birth (Bushnell, 2001; Pascalis, de Schonen, Morton, Deruelle, & Fabre-Grenet, 1995). Full face processing abilities clearly take several years to develop.

In this paper we show that a single learning system can account for all three types of results, i.e. face preferences at birth, face learning in the first few days after birth, and the gradual development of full face processing abilities. Using the HLISSOM self-organizing model (Hierarchical Laterally Interconnected Synergetically Self-Organizing Map), we have previously shown how prenatal learning of spontaneous neural activity can lead to newborn face preferences (Bednar & Miikkulainen, 2000). In this paper we show that the same self-organizing system can learn from faces in real images, and that the learning process can explain postnatal changes in infant face detection abilities. Together these simulations show how genetic information can be expressed within a highly adaptive system, and provide concrete predictions for future experiments with infants.

Development of face detection

Face detection abilities change significantly between birth and two months of age. When shown moving schematic faces

in the visual periphery, newborns and one month olds will follow them further than other similar patterns (Goren et al., 1975; Johnson et al., 1991; see example schematics in figure 5a-d). Older infants do not show a peripheral schematic face preference (Johnson et al., 1991) but between one and two months they begin to respond to facial features in central vision (Maurer & Barrera, 1981).

Previous models invoke separate visual processing mechanisms for these newborn and later face preferences. For instance, Johnson and Morton (1991) proposed that infants are born with a simple subcortical system they termed CONSPEC. CONSPEC serves only to detect and direct attention to face-like patterns in the periphery, perhaps using a simple three-dot template (two dots for the eyes and a third for the nose and mouth). A separate cortical system CONLERN would begin to control behavior after one month, and would gradually develop more sophisticated face processing through learning in central vision.

However, the CONSPEC/CONLERN model does not account for neonatal face learning. For instance, an infant only a few days old will prefer to look at its mother's face, relative to the face of a stranger (Pascalis et al., 1995). This mother preference has been thought to involve the external outline of the face only, in contrast to the internal facial feature learning of CONLERN, because the preference disappears when internal features are masked (Pascalis et al., 1995).

Accordingly, Johnson and Morton (1991) and subsequent authors have proposed extending the CONSPEC/CONLERN model to include face-outline learning in CONSPEC, or a third, separate subsystem for learning face outlines at birth (de Schonen, Mancini, & Legeois, 1998; Simion et al., 1998). However, recent studies suggest that newborns can also learn internal features (Slater, Bremner, Johnson, Sherwood, Hayes, & Brown, 2000). Such learning could require a fourth subsystem, like CONLERN but for the periphery and operational at birth. (CONLERN itself cannot explain newborn learning of internal features, because were it present at birth, it would no longer explain the shift from peripheral to central face preferences after one month.)

We will show that such increasingly complex models are unnecessary. A single, CONLERN-like system processing the entire visual field is sufficient to explain the experimental data, if CONSPEC is replaced by a system that generates training patterns before birth. We have previously shown that a system trained on such spontaneous activity can account for the measured face preferences of newborns (Bednar, 2002; Bednar & Miikkulainen, 2000). The 3 hypotheses of the present paper are that: (1) networks trained on spontaneous activity learn more robustly after birth, compared to systems exposed only to environmental stimuli, (2) the decline in re-

Figure 1: **HLISSOM model of face detection.** The model is a hierarchy of sheets of neural units, modeling the infant visual pathway. The model learns in two phases, each driven by input from a different source. During prenatal learning (a), activity originates internally in the PGO pattern generator. In postnatal learning (b), visual images are drawn on the photoreceptor sheet. For either type of input, the LGN is strongly activated by high-contrast edges and borders. The FSA is activated by the strongly responding units in the LGN, and activity then spreads laterally within the FSA. FSA weights are adapted when the activity settles. The FSA weights are initially uniform and unselective, but through self-organization they become selective for facelike patterns at the corresponding location on the retina. Their response is then information that an organism can use directly to control behaviors like visual fixation.

sponse to schematic patterns after one month results from learning of real faces and their outlines, not from a shift to a separate system, and (3) learning of both facial features and outlines can explain the development of a mother preference, including why it disappears when the outline is masked. Each of these hypotheses will be tested in a computational experiment with the HLISSOM model. Together the experiments will show that infant face learning and face preferences can be explained by a single, general-purpose learning system, which learns from both internally generated patterns of activity and from the visual environment.

HLISSOM Model

The architecture for the HLISSOM model is shown in figure 1, and will be briefly reviewed below. (For more details, see Bednar, 2002.) The model consists of a hierarchy of two-dimensional sheets of neural units modeling different areas of the nervous system: two sheets of input units (the retinal photoreceptors and the ponto-geniculo-occipital (PGO) pattern generator, described under *Prenatal learning* below), two sheets of LGN units (ON-center and OFF-center), and a sheet of cortical units ("neurons") representing a high-level area, the face-selective area (FSA)¹. Each FSA neuron corresponds to a vertical column of cells through the six anatomical layers of the cortex.

¹The FSA represents the first region in the ventral processing pathway that has receptive fields spanning approximately 45° of visual arc, i.e. large enough to span a human face at close range. Areas V4v and LO are likely FSA candidates based on adult patterns of connectivity, but the infant connectivity patterns are not known (Rolls, 1990). The generic term "face-selective area" is used rather than V4v or LO to emphasize that the model results do not depend on the region's precise location or architecture, only on the fact that the region has receptive fields large enough to allow face-selective responses. Cortical areas between the LGN and the FSA have been bypassed for simplicity; see Bednar (2002) for a more complex model including the primary visual cortex (V1).

The input to the model is an activity pattern on a sheet of photoreceptors or the PGO generator (see examples in figure 1). Each cell (i, j) in the ON- and OFF-center layers of the LGN computes its response η_{ij} as a scalar product of a fixed weight vector and its receptive fields on each input sheet:

$$\eta_{ij} = \sigma \left(\sum_{\rho ab} \gamma_{\rho} X_{\rho ab} w_{ij, \rho ab} \right), \quad (1)$$

where σ is a piecewise linear sigmoid activation function, ρ specifies the input sheet (either photoreceptors or PGO), γ_{ρ} is a constant scaling factor, $X_{\rho ab}$ is the activation of input unit (a, b) on sheet ρ , and $w_{ij, \rho ab}$ is the corresponding weight value. The lower bound δ of the sigmoid acts as an activation threshold; there is no response for activation below δ . Each FSA neuron computes its initial response like that of an LGN cell, except that ρ is either the ON or OFF LGN layer. After the initial response, the FSA activity evolves through short-range excitatory and long-range inhibitory lateral interaction:

$$\eta_{ij}(t) = \sigma \left(\sum_{\rho ab} \gamma_{\rho} X_{\rho ab}(t-1) w_{ij, \rho ab} \right), \quad (2)$$

where ρ specifies the weight type (either ON channel afferent, OFF channel afferent, lateral excitatory, or lateral inhibitory), γ_{ρ} is a constant scaling factor for each weight type (negative for inhibitory lateral weights), and $X_{\rho ab}(t-1)$ is the activation of target unit (a, b) during the previous time step. The FSA activity pattern starts out diffuse, but within a few iterations of equation 2, converges into a small number of stable focused patches of activity, or activity bubbles (as in figure 1). After the activity has settled, the connection weights of each FSA neuron are modified. All FSA weights adapt according to the Hebb rule, normalized so that the sum of the weights of each type ρ is constant for each neuron (i, j) :

$$w_{ij, \rho ab}(t + \Delta t) = \frac{w_{ij, \rho ab}(t) + \alpha_{\rho} \eta_{ij} X_{\rho ab}}{\sum_{ab} [w_{ij, \rho ab}(t) + \alpha_{\rho} \eta_{ij} X_{\rho ab}]}, \quad (3)$$

where η_{ij} stands for the activity of neuron (i, j) in the final activity bubble, $w_{ij, \rho ab}$ is the connection weight, α is the learning rate for each type of connection, and $X_{\rho ab}$ is the presynaptic activity. The larger the product of the pre- and post-synaptic activity $\eta_{ij} X_{\rho ab}$, the larger the weight change.

For these experiments, a pair of 74×74 ON-center and OFF-center cell layers received input from a 170×170 photoreceptor sheet and an 85×85 PGO sheet. Each ON/OFF cell had a fixed Difference of Gaussians receptive field (RF) within the photoreceptor array (center $\sigma = 0.75$, surround $\sigma = 1.2$). The 24×24 FSA neurons each had a circular afferent receptive field of size 25, centered on the location in the central 24×24 portion of the ON/OFF cell layer corresponding the neuron's location in the FSA. This mapping ensures that every neuron has a complete set of circular afferent connections. Initially, the afferent and lateral weights in the FSA had a smooth circular Gaussian profile, and all weights of each type were identical. Other parameters were from Bednar and Miikkulainen (2000), scaled for this cortex size using the equations from Bednar (2002).

Prenatal learning

The simulations in this paper focus on postnatal learning, but they continue from our earlier results on prenatal learning (Bednar & Miikkulainen, 2000), which we summarize

Figure 2: Starting points for postnatal learning. These plots show the RFs for every third neuron from the 24×24 array of neurons in the FSA. For the prenatally trained network (a), the RFs were visualized by subtracting the OFF weights from the ON. The result is a plot of the retinal stimulus that would most excite that neuron. Like CONSPEC, the prenatally trained network consists of an array of roughly facelike RFs. In contrast, the neurons in the naïve network are initially uniformly Gaussian. The ON and OFF weights were identical, so only the ON weights are shown in (b). Later figures will compare the postnatal learning of each network.

here. We hypothesize that before birth, training patterns arise from ponto-geniculo-occipital (PGO) waves generated during rapid-eye-movement (REM) sleep. Developing embryos spend a large percentage of their time in a precursor of REM sleep, which suggests that this state has a major role in development (Roffwarg, Muzio, & Dement, 1966). During and just before REM sleep, PGO waves originate in the brain stem and travel to the LGN, visual cortex, and many other brain areas (see Callaway, Lydic, Baghdoyan, & Hobson, 1987 for a review). PGO waves are strongly correlated with eye movements and with vivid visual imagery in dreams, suggesting that they activate the visual system as if they were visual inputs (Marks, Shaffery, Oksenberg, Speciale, & Roffwarg, 1995). PGO waves elicit different distributions of activity in different species, and interrupting them has been shown to increase the influence of the environment on development (Marks et al., 1995).

All of these characteristics suggest that PGO waves may be providing species-specific training patterns for development (see Bednar, 2002 for more details). However, due to limitations in experimental imaging equipment and techniques, the spatial shape of the PGO wave activity patterns has not yet been measured. Based on the CONSPEC model, we chose the three-dot patterns illustrated in the PGO area of figure 1a. Other patterns are also possible, and will provide greater or lesser face selectivity (Bednar, 2002).

As described in previous work (Bednar & Miiikkulainen, 2000), FSA neurons exposed to prenatal patterns developed receptive fields (RFs) preferring upright, triangular arrangements of three dots (figure 2a). The resulting map responds to most frontal face images, and not to most objects or backgrounds. At this stage, the trained map can be considered an implementation of CONSPEC, except that it was constructed by learning and will continue to learn after birth.

To determine whether the prenatal training biases subsequent learning (hypothesis 1 above), we also simulated a control condition called the *naïve* network. The naïve network

Figure 3: Sample postnatal learning iterations. The top row shows six randomly generated images drawn on the retinal photoreceptors at different iterations. Each image contains a foreground item chosen randomly from a set of three men and three women (adapted from Rowley et al., 1998) and six object images (from public domain clip art collections). Each foreground item was overlaid onto a random portion of an image from a database of 58 natural scenes (National Park Service, 1995), at a random location and at a nearly vertical orientation (drawn from a normal distribution around vertical, with $\sigma = \pi/36$). The second row shows the LGN response to each of these sample patterns, visualized by subtracting the OFF cell responses from the ON cell responses. Dark areas indicate high OFF cell response, light indicate high ON cell response, and medium gray indicates no response. The bottom row shows the prenatally trained FSA response to each pattern, at the start of postnatal training. For the FSA, only neurons with complete receptive fields (those in the unshaded inner box) were simulated, because those in the gray area would have RFs cut off by the edge of the retina. The gray area shows the FSA area that corresponds to the same portion of the visual field as in the LGN and retina plots, to facilitate comparison. The FSA responds to groups of dark spots on the retina, such as the eyes and mouths in (b-c,f) and the horse's markings in (d); the location of the FSA activity corresponds to the position of the group of retinal patterns that caused the response.

is so called because it models neurons that have not had experience with coherent activity patterns until after birth. So that the naïve and prenatally organized networks would match on as many parameters as possible, we constructed the naïve network from the prenatally trained network *post hoc* by explicitly resetting afferent receptive fields to their uniform-Gaussian starting point (figure 2b). This procedure removed the prenatally developed face selectivity, but kept the lateral weights and all of the associated parameters the same. The activation threshold δ for the naïve FSA network was then adjusted so that for a given training pattern both networks would have similar activation levels; otherwise the parameters were the same for each network. This procedure ensures that the comparison between the two networks will be as fair as possible, because besides the thresholds the networks differ only by whether the neurons have face-selective weights at birth.

Postnatal testing and learning

The postnatal learning experiments reported in this paper simulate gradual learning of specific individuals and objects seen against a variety of different backgrounds. Figure 3 shows samples of the images we used and describes how they were generated. The prenatally trained and naïve networks were each exposed to the same pseudorandom sequence of 30,000 of these images.

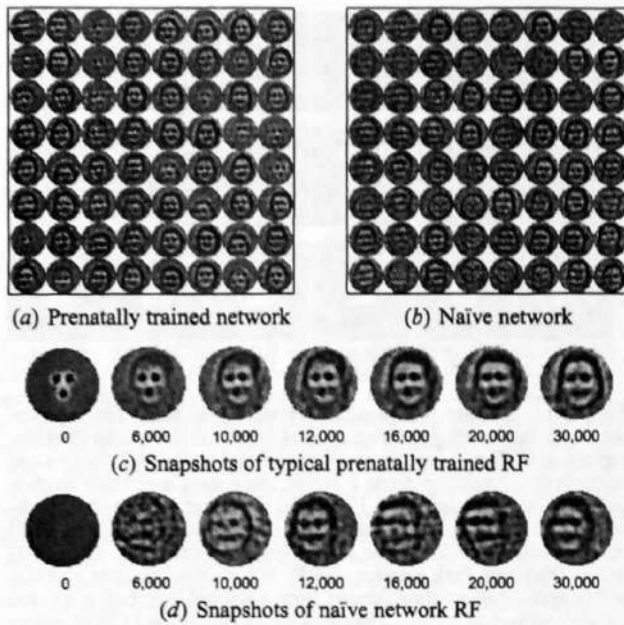

Figure 4: Prenatal patterns bias postnatal learning in the FSA. Plots (a) and (b) show the final RFs for every third neuron from the 24×24 array of neurons in the FSA, visualized as in figure 2a. As the prenatally trained network learns from real images, the RFs morph smoothly into prototypes, i.e. representations of average facial features and hair outlines (c). By postnatal iteration 30,000, nearly all neurons have learned face-like RFs, with very little effect from the background patterns or non-face objects (a). Postnatal learning is less uniform for the naïve network, as can be seen in the RF snapshots in (d). In the end, many of the naïve neurons do learn face-like RFs, but others become selective for general texture patterns, and some become selective for objects like the clock (b). Overall, the prenatally trained network is biased towards learning faces, while the initially uniform network more faithfully represents the environment. Thus prenatal learning can allow the genome to guide development in a biologically relevant direction.

At the beginning of the postnatal phase, and at intervals throughout, we tested the network using schematic images previously tested with newborns, and with photographs of faces. In order to compare the neural activity in the model to babies' attentional preferences, we assume that newborns pay more attention to the stimuli that are most effective at activating their visual processing system, focusing on the highest level activated. Patterns activating the FSA will be preferred over those activating only lower areas, and patterns that both activate the FSA will be ranked by their FSA activity. We quantify these comparisons by presenting each stimulus 25 times at different retinal locations, and averaging the sum of the FSA activity. As in the psychological studies we are modeling, differences between patterns will be tested with the two-tailed Student's *t*-test, treating *p* values below 0.05 as significant.

Results

Experiment 1: Bias from prenatal learning

Figure 4 shows that with postnatal exposure to real images, both the naïve and prenatally trained networks develop RFs that are averages (i.e. prototypes) of faces and hair outlines. RFs in the prenatally trained network smoothly increase in

Figure 5: Decline in response to schematic faces. Before postnatal training, the prenatally trained FSA (third row from top) responds significantly more to the facelike stimulus (a) than to the three-dot stimulus (b; $p = 0.05$) or the scrambled faces (c-d; $p = 10^{-8}$). Assuming that infants attend most strongly to the stimuli that cause the greatest neural response, these responses replicate the schematic face preferences found by Johnson and Morton (1991) in infants up to one month of age. Some of the Johnson & Morton, 1991 experiments found no significant difference between (a) and (b), which is unsurprising given that they are only barely significantly different here. As the FSA neurons learn from real faces postnatally, they respond less and less to schematic faces. The bottom row shows the FSA response after 1000 postnatal iterations. The FSA now rarely responds to (a) and (b), and the average difference between them is no longer significant ($p = 0.25$). Thus no preference would be expected for the facelike schematic after postnatal learning, which is what Johnson and Morton (1991) found for older infants, i.e. 6 weeks to 5 months old. The response to real faces also decreases slightly through learning, but to a much lesser extent (e-f). The response to real faces declines because the newly learned average face and hair outline RFs are a weaker match to any particular face than were the original three dot RFs. That is, the external features vary more between individuals than do the internal features, and thus their average is not a close match to any particular face. Even so, there is only a comparatively small decrease in response to real faces, because real faces are still more similar to each other than to the schematic faces. Thus HLISSOM predicts that older infants will still show a face preference if tested with more-realistic stimuli, such as photographs.

face selectivity, and eventually nearly all become highly selective for faces (figure 4b). Postnatal self-organization in the naïve network is less regular, and the final result is less face selective. Thus prenatal training biases postnatal learning towards biologically relevant stimuli, i.e. faces (hypothesis 1).

Experiment 2: Decline in response to schematics

Figure 5 shows that the HLISSOM model replicates the disappearance of peripheral schematic face preferences after one month (hypothesis 2; Johnson et al., 1991). In HLISSOM, the decrease results from the afferent weight normalization (equation 3). As the FSA neurons in HLISSOM learn the hair and face outlines typically associated with real faces, the connections to the internal features necessarily become weaker. Unlike real faces, the facelike schematic patterns match only on these internal features, not the outlines. As a result, the response to schematic facelike patterns decreases as real faces

are learned. Eventually, the response to the schematic patterns approaches and drops below the fixed activation threshold δ . At that point, the model response is no longer higher for schematic faces (because there is no FSA response, and V1 responses are similar). In a sense, the FSA has learned that real faces typically have both inner *and* outer features, and does not respond when either type of feature is absent or a poor match to real faces.

Yet the FSA neurons continue to respond to real faces (as opposed to schematics) throughout postnatal learning (figure 5e-f). Thus the model provides a clear prediction that the decline in peripheral face preferences is limited to schematics, and that if infants are tested with sufficiently realistic face stimuli, no decline in preferences will be found.

Experiment 3: Mother preferences

Figure 6a-b shows that when one face (i.e. the mother) appears most often, the FSA response to that face becomes stronger than to a similar stranger. This result replicates the mother preference found in infants a few days old (hypothesis 3; Bushnell, 2001; Pascalis et al., 1995). Interestingly, figure 6c-d shows that the mother preference disappears when the hair outline is masked, which is consistent with Pascalis et al.'s claim that newborns learn outlines only. However, Pascalis et al. (1995) did not test the crucial converse condition, i.e. whether newborns respond when the facial features are masked, leaving only the outlines. Figure 6(e-f) shows that there is no response to the head and hair outline alone either, and thus that this face learning is clearly *not* outline-only.

In the model, the decreased response with either type of masking results from holistic learning of *all* of the features typically present in real faces. As real faces are learned, the afferent weight normalization ensures that neurons respond only to patterns that are a good overall match to all of the weights, not simply matching on a few features. Many authors have argued that adults also learn faces holistically (e.g. Farah et al., 1998). These results suggest that newborns may learn faces in the same way, and predict that newborns will no prefer their mother when her hair outline is visible but her facial features are masked.

Discussion and future work

The HLISSOM simulations show that internally generated patterns and a self-organizing system can together account for newborn face preferences, neonatal face learning, and longer term development of face detection. The results suggest simple but novel explanations for why newborn learning appears to depend on the face outline, and why the response to schematic faces decreases over time. These explanations lead to concrete predictions for future infant experiments. Over the first two months the response to real faces in the periphery should continue even as response to schematics diminishes, and the mother preference of newborns should disappear when the facial features are masked. The results also show that internally generated patterns allow the genome to steer development towards biologically relevant processing, making learning of more sophisticated abilities quicker and more robust.

The results above do not address one interesting phe-

Figure 6: Mother preferences depend on both internal and external features. Initially, the prenatally trained FSA responds well to both women above (a-b; FSA-0), with no significant difference ($p = 0.28$). The response is primarily due to the internal facial features (c-d; FSA-0), although there are some spurious three-dot responses due to alignment of the hair with the eyes (a-b; top of FSA-0). Designating image (a) as the mother, we presented it in 25% of the postnatal learning iterations. (This ratio is taken from Bushnell, 2001, who found that newborns look at their mother's face for an average of about one-fourth their time awake over the first few days.) Image (b), the stranger, was not presented at all during training. After 500 postnatal iterations, the response to the mother is significantly greater than to face (b) ($p = 0.001$). This result replicates the mother preference found by Pascalis et al. (1995) in infants 3–9 days old. The same results are found in the counterbalancing condition — when trained on face (b) as the mother, (b) becomes preferred ($p = 0.002$; not shown). After training with real faces, there is no longer any FSA response to the facial features alone (c-d), which replicates Pascalis et al.'s (1995) finding that newborns no longer preferred their mother when her face outline was covered. Yet contra Pascalis et al. (1995), we cannot conclude that what has been learned “has to do with the outer rather than the inner features of the face”, because no preference is found for the face outline alone either (e-f). Thus face learning in HLISSOM is holistic. Face learning in adults is also thought to be holistic (Farah et al., 1998), and these results show that we do not need to assume that newborns are using a different type of face learning than adults.

nomenon: in central vision, preference for schematic faces is not measurable until 2 months of age (Maurer & Barrera, 1981), and is gone by 5 months (Johnson et al., 1991). This time course is delayed relative to peripheral vision, where preferences are present at birth but disappear by 2 months.

Johnson and Morton (1991) originally proposed that in the periphery the preferences disappear because CONLERN matures and inhibits CONSPEC, while in central vision they disappear because CONLERN learns properties of real faces. HLISSOM provides a unified explanation for both phenomena: a single learning system stops responding to schematic faces because it has learned from real faces.

Why, then, would the time course differ between peripheral and central vision? As Johnson and Morton acknowledged, the retina changes significantly over the first few months. In particular, at birth the fovea is much less mature than the periphery, and may not even be functional yet (Abramov, Gordon, Hendrickson, Hainline, Dobson, & LaBossiere, 1982; Kiorpes & Kiper, 1996). Thus schematic face preferences

in central vision may be delayed relative to those in peripheral vision simply because the fovea matures later. A single cortical learning system like HLISSOM is thus sufficient to account for the time course of both central and peripheral schematic face preferences.

The development of the fovea may also affect mother preferences. Consistent with our results, Bartrip, Morton, and de Schonen (2001) found that infants 19–25 days old do not significantly prefer their mothers when either her internal features or external features are covered. Interestingly, Bartrip et al. found that older infants, 35–40 days old, do prefer their mothers even when the external features are covered. The gradual maturation of the fovea may again explain these later-developing capabilities. Unlike the periphery, the fovea contains many ganglia with small RFs, and which connect to cortical cells with small RFs. These neurons can learn smaller regions of the mother's face, and their responses will allow the infant to recognize the mother even when other regions of the face are covered. Thus simple, documented changes in the retina can explain why mother preferences would differ over time.

In general, the idea that artificially generated training patterns can influence the development of learning systems is powerful, and could be used to construct artificial systems as well. Simple, engineered training patterns can provide an initial or ongoing bias, while learning algorithms incorporate the full complexity of the environment. This approach can allow more complex adaptive systems to be designed and implemented.

Conclusion

A single learning system can explain the seemingly complex postnatal time course of face processing, if that system is exposed to internally generated patterns. Initial face selectivity develops from these non-visual inputs, and postnatal experience interacts with these genetic factors to develop full face processing abilities. These results provide clear predictions for future infant experiments, and provide new tools for constructing complex artificial systems.

Conditional Promises and Threats – Cognition and Emotion

Sieghard Beller (beller@psychologie.uni-freiburg.de)

Department of Psychology, University of Freiburg
D-79085 Freiburg, Germany

Abstract

Conditional promises and threats are speech acts that can be used to manipulate the behavior of other persons. Although reasoning studies have been able to reveal some peculiarities of these concepts, the *explanation* has remained fragmentary. To fill in this gap, a theoretical analysis of conditional inducements is proposed, which integrates cognitive as well as emotional aspects. An experiment – focussing on linguistic, pragmatic, emotional, and deontic consequences – corroborates the analysis and shows that persons have a clear understanding of conditional inducements.

Introduction

Conditional promises and threats are speech acts (Searle, 1971) uttered by a person to manipulate an addressee's behavior by setting up consequences of his behavior (cf. Conison, 1997; von Wright, 1962). Walking home from school, Henry may make the following proposal to his classmate Bob:

- (1) "If you lend me your bike,
then I will help you with your homework".

Bob can infer from this statement that Henry would like to borrow his bike, and that Henry believes that he (Bob) needs Henry's help.

Research on human reasoning usually focusses on the *inferential* use of conditional promises/threats within the normative framework of propositional logic: Which inferences do people draw from conditional arguments? Suppose, (2) Bob *lends* Henry his bike. What follows then from (1) and (2)? Will Henry help Bob? – Although we cannot know for sure which action a person will actually take, we would expect that Henry *will* help him, or at least we think that he *will have to*. This answer is logically warranted by *Modus Ponens* (MP). But what should be concluded from the promise (1), if (3) Bob *does not* lend out his bike? Usually, persons answer that Henry *will not* help Bob either. This inference, however, corresponds to a logically invalid pattern known as *Denial of the Antecedent* (DA).

In general, the valid MP and MT (*Modus Tollens*) as well as the invalid DA and AC (*Affirmation of the Consequent*) are drawn more frequently from conditional promises and threats than from universal conditionals (e.g., Fillenbaum, 1978; Markovits & Lesage, 1990; Newstead, Ellis, Evans, & Dennis, 1997; but see Evans & Twyman-Musgrove, 1998, for a diverging result).

Most people accept the complementary conditional 'If not-P, then not-Q' as following from inducements of the form 'If P, then Q' (Fillenbaum, 1978). Geis and Zwicky (1971) speak of "invited inferences" in normal linguistic usage. Accordingly, the associated truth tables often reflect an equivalence relation instead of an implication (Newstead et al., 1997).

Treating conditional inducements in this way enables one to *detect* effects of different propositional contents on reasoning, but it is not sufficient to *explain* the underlying causes. What is the reason for the DA inference in the introductory example? Furthermore, a simple truth-table analysis is much too restricted to capture conceptual aspects of conditional inducements beyond the if-then relation. Why, for example, is Henry *obliged* to help Bob under certain circumstances? How will Bob react *emotionally* if Henry does not help him? A detailed theoretical analysis is presented to overcome these limitations. It integrates several aspects on different levels: goals and incentives on the motivational level, formulations and inferences on the linguistic level, obligation and permission on the deontic level, action sequences on the pragmatic level, and finally, affective reactions on the emotional level. The multi-level analysis explains the phenomena observed in reasoning studies; new phenomena are predicted and experimentally confirmed.

Levels of Conditional Inducements

(1) **Motivational level:** The basic level of analysis concerns the motivational situation in which a person utters an inducement. It is determined by *expectations*, *goals* and *incentives*. The speaker (S) wants an addressee (A) to show a certain *goal-behavior* (i.e., to perform a certain action or to refrain from performing an action) with a positive value for himself, the speaker (S+: Behavior_A). In the introductory example, it was Henry who wanted Bob to lend him his bike. Henry must expect that the addressee is not willing to show this behavior voluntarily, otherwise an inducement would not be necessary. Thus, the speaker has to induce a behavioral change:

Expected behavior (grey boxes)	S-: ¬Behavior _A
↓	
Goal of the speaker S	S+: Behavior _A

This change can be motivated in two ways: First, the speaker may promise to *reward* the *desired* goal behavior S+ with a positive consequence for the addressee

(\Rightarrow A+: Reward_S). Believing that Bob needs help with his homework, Henry may promise to help him (A+) if Bob lends him his bike (S+). The reward should be under the speaker's control and should *not* occur for any other reason, as otherwise it cannot develop its motivational effect (e.g., Evans & Twyman-Musgrove, 1998). The whole motivational schema may be represented as:

Promise	S-: \neg Behavior _A	A-: \neg Reward _S
	S+: Behavior _A	\Rightarrow A+: Reward _S

Instead of rewarding the desired behavior, the speaker may *punish* the *undesired* behavior he fears (S-) with a negative consequence (A-). If he usually helps Bob with his homework, Henry can use Bob's expectation and threaten to withdraw his help (A-) if Bob does not lend him his bike (S-). The corresponding schema is:

Threat	S-: \neg Behavior _A	\Rightarrow A-: Punishment _S
	S+: Behavior _A	A+: \neg Punishment _S

In both cases, the speaker announces (explicitly or implicitly) that he will react positively (A+) if the addressee shows the desired behavior (S+), and negatively otherwise. There is an essential difference, however: If the addressee cooperates (S+), then in the first case he *gets* something he cannot expect without the promise (the reward A+), whereas in the second case he only *avoids* the punishment (A-) without getting anything positive in return.

(2) **Linguistic level:** The motivational schemas directly determine which formulations are appropriate to express the intended speech act. Conditionals 'If P, then Q' can be used equally well with both schemas. Conditionals point out a necessary consequence 'Q' of an antecedent condition 'P', and that is exactly what the speaker intends on the motivational level: to establish a new, definite consequence for one of the addressee's behavioral options. The canonical formulations are:

"If you do P [S+], then I will reward you with Q [A+]" vs.
 "If you do P [S-], then I will punish you by Q [A-]".

Looking at the underlying motivational schemas, it becomes clear why the complementary form 'If not-P, then not-Q' is inferred, and why conditional inferences (MP, MT, DA, AC) seemingly correspond to an equivalence relation. The motivational level suggests that there are two action sequences: a cooperative one and a not-cooperative one. The complementary conditional reflects that part of the motivational background that is not expressed explicitly by the canonical statement. Together, the canonical and the complementary conditional yield the equivalence interpretation. Different from a logical equivalence, however, the reversed form (e.g., "If I reward you with Q [A+], then you will do P [S+]") is not really equivalent to the canonical one. By reversing antecedent and consequent, the temporal order

changes as well, so that the speaker can no longer guarantee that action 'P' is a necessary consequence of the antecedent event 'Q' ('P' is not under his control).

The differences between the motivational schemas also explain why only threats are formulated disjunctively, whereas both promises and threats can be formulated conjunctively (Fillenbaum, 1978). The *conjunctive* formulation expresses the connection between the new consequence set by the speaker and the addressee's behavior:

"Do P [S+] and I will reward you with Q [A+]" vs.
 "Do P [S-] and I will punish you by Q [A-]".

A *disjunction* points out alternatives. In the case of a threat, it enables the speaker to express both his goal S+ and the punishment A-, which are part of alternative action sequences: "Refrain from doing P [S+] or I will punish you by Q [A-]". If a promise were to be reformulated disjunctively, then either the speaker's goal or his reward could no longer be expressed.

(3) **The deontic level** deals with the question of which action a person *may* or *must* perform with respect to a social rule (e.g., Beller, 2001). Conditional promises and threats establish such a rule and determine which actions persons are obliged to perform. Since the addressee can freely decide whether or not he cooperates, there is *no* deontic constraint on his behavior. He *may* cooperate, but he *need not*. The speaker's situation is different. Consider the promise

"If you do P [S+], then I will reward you with Q [A+]".

Once the addressee cooperates and fulfills the speaker's goal 'P', the promisor is *obliged* to cooperate and to give reward 'Q'. The promisor himself declared 'Q' to be a necessary consequence of condition 'P', so he *must* guarantee the reward. If the addressee does not cooperate, then there is *no* deontic constraint; the speaker *need not* give the reward, but he is *permitted* to do it voluntarily. Which obligation, however, results from a threat

"If you do P [S-], then I will punish you by Q [A-]"?

Two lines of argumentation are possible here: First, arguing analogously to the promise, the speaker is *obliged to punish* the addressee ('Q') if A does *not* cooperate ('P'). The speaker declared punishment 'Q' to be a necessary consequence of condition 'P', so he *must* react consequently (and indeed perhaps he should, in order to keep his credibility). What is the case if the addressee *cooperates*? By analogy, there is *no* constraint on the speaker's action, so he *need not* punish the addressee, but he actually *may* punish him. An implicit social rule, however, intuitively contradicts this interpretation: A person *must not* be punished without reason, whereas one *may* well give a reward without reason.

Second, it can be argued that the threat implies a *complementary promise* that determines the deontic interpretation: "If you *refrain from* doing 'P' [S+], then I will *not* punish you by Q [A-]". Associated with a promise is an obligation for the speaker to cooperate (A+) once

the addressee has fulfilled his goal (S+). If the addressee refrains from doing 'P' (S+), then the speaker *must* refrain from the punishment. If the addressee does not cooperate, then there is no deontic constraint and the speaker is *permitted* to punish the addressee. Since the punishment is now justified, this interpretation is in line with the implicit social rule mentioned above.

(4) **The pragmatic level** deals with the question of which actions are actually taken after an inducement has been uttered. Since both persons are assumed to have full freedom of action, four action sequences are possible: If the addressee fulfills the speaker's goal (S+), then subsequently the speaker may also cooperate (A+) or may not (A-). If the addressee does *not* show the goal behavior (S-), then the speaker may not cooperate either (A-) or may cooperate (A+). Common to all four sequences is a particular *temporal order*: The addressee decides first whether he wants to cooperate, whereas the speaker has to react to the addressee's behavior.

(5) **Emotional level**: Eventually, one of the four action sequences follows a conditional inducement. Each sequence is characterized by goals, expectations and incentives. These factors are directly relevant for the elicitation of emotions (e.g., Lazarus, 1991; Roseman, Antoniou & Jose, 1996). Goal-relevance is a necessary requirement for emotional reactions in general; goal-congruent events elicit positive emotions, while goal-incongruent events elicit negative emotions. Applied to conditional promises and threats, addressee and speaker should feel a positive emotion if the partner cooperates (and fulfills their goal or expectation), while a negative emotion should result if the partner does not cooperate. Which specific emotion arises in a given situation depends on further appraisal dimensions that cannot be described in detail here (for extensive analyses see, e.g., Roseman et al., 1996). Summarizing those studies though, *joy* can be expected when a person gets something positive, *relief* when an expected negative event does not occur, and *anger* when the partner does not cooperate even though he or she is obliged to.

Experiment

The proposed multi-level analysis integrates motivation, linguistics, pragmatics, deontic considerations, and emotions, thereby overcoming the limitations of a purely truth functional analysis of conditional promises and threats. In order to test hypotheses regarding particular facets of the analysis, an experiment was conducted which consisted of two parts.

The starting point of part I was an influential finding of Leda Cosmides (1989). Cosmides showed with domain-specific versions of Wason's (1966) selection task that persons are sensitive to which of the partners involved in a reciprocal exchange is accused of breaking his promise, but *not* to the conditional formulation. It did not make a difference whether the promise was formulated canonically or reversed. The multi-level analysis makes just the opposite prediction; namely that

persons should be sensitive to the formulation of inducements. A reversed inducement is *not* equivalent to the original one, since it also implies a reversal of the temporal order and of the roles (*speaker-addressee-asymmetry*): Given a particular role allocation, the canonical conditional should be preferred to the reversed one, the complementary conditional (and not the reversed one) should be preferred as implication, and the action sequence should be "addressee first". In addition, it was assessed which *emotional reactions* persons attribute to the addressee if the speaker keeps or breaks "the rule".

Part II of the experiment focusses on an aspect that has not been explored until now: the *deontic inferences* people draw from conditional promises and threats. The prediction for promises is clear: If the addressee has fulfilled the speaker's goal, then an obligation arises for the speaker to give the promised reward; otherwise there is no such obligation. The deontic interpretation of conditional threats, however, is not equally clear. Do people infer (from the conditional form) an obligation for the speaker to punish the addressee A if A does not cooperate, or do they rather infer (from the *complementary* promise) an obligation to cooperate and refrain from the punishment if the addressee cooperates? It was expected that the second interpretation would predominate since it is not in conflict with general moral rules.

Method

Both parts of the experiment were integrated into one questionnaire. They used different basic scenarios from which four context stories each were constructed. The stories in part I dealt with the exchange situation mentioned in the introductory example (help with homework in exchange for borrowing a bike) but varied with regard to role allocation and speech act. Four tasks had to be solved, which focussed on the linguistic, pragmatic and emotional level. The context stories in part II were constructed from two different scenarios; one dealt with mutual lending of things and the other with mutual destruction of toys. Again, the speech acts varied, but this time only one role allocation was used. Four tasks asked for deontic inferences from the inducements. To facilitate the discussion of the results, stories and tasks for both parts are described later in separate sections.

Participants: 40 students from two introductory cognitive psychology courses (at the University of Freiburg) participated in the experiment. 18 students were male and 22 female, with a mean age of $M = 23.8$ years (range: 20-39 years).

Design: Participants were randomly assigned to one of four groups ($n = 10$). The four context stories of each part varied between groups. The speech acts were balanced within groups: If part I was about a promise then part II dealt with a threat (and vice versa).

Procedure: The questionnaire was administered at the beginning of the first course session. After a general instruction on the first page, the questionnaire began with the tasks of part I, followed by the tasks of part II.

The tasks were ordered as described below and each was written on a new page. Participants were instructed to work on the tasks in the given order, and to take as much time as needed. All materials were presented in German.

Part I: Assessing the Speaker-Addressee-Asymmetry and Emotional Reactions

In order to assess the speaker-addressee-asymmetry, four context stories were designed, which were similar to the introductory exchange scenario. The stories described the person's goals and their usual behavior; they varied with regard to the intended speech act (promise vs. threat) and the roles (speaker vs. addressee). In two stories, Henry wants to borrow Bob's bike. He tries to achieve this goal either by a promise or by a complementary threat (canonical conditionals: "If you lend me your bike, then I will help you with your homework" vs. "If you do *not* lend me your bike, then I will *not* help you with your homework"). In the other two stories, the roles were interchanged: This time, Bob wants Henry to help him with his homework and he tries to achieve this goal by the reversed promise or threat ("If you help me with my homework, then I will lend you my bike" vs. "If you do *not* help me with my homework, then I will *not* lend you my bike"). Each story was followed by four tasks.

(1) **Formulation task:** In the first task, the motivational background was given together with the type of speech act to be used. The participants were then instructed to choose from four given conditionals the one that was most appropriate for the speaker's intended inducement. The conditionals were derived from the canonical one by reversing and negating 'P' and 'Q'. Table 1 shows the results. As predicted, the canonical conditionals were clearly preferred (90% aggregated over all context stories). If the speech act changed then the complementary conditional was chosen, whereas if the role allocation changed then the reversed form was preferred.

(2) **Inference task:** From this task onwards, the context stories had been supplemented by the canonical conditional. The instruction called for participants to choose an adequate implication of the given conditional

Table 1: Frequency of choosing each conditional as the speaker's adequate promise or threat ($n = 10$ in each condition; canonical conditionals are **bold-faced**).

Conditional	Henry's		Bob's	
	Promise	Threat	Promise	Threat
<i>If bike then help</i>	10	1	-	-
<i>If no bike then no help</i>	-	9	-	-
<i>If help then bike</i>	-	-	10	3
<i>If no help then no bike</i>	-	-	-	7

Table 2: Frequency of choosing the most adequate implication of a given promise or threat ($n = 10$ in each condition; complementary inducements are **bold-faced**).

Conditional	Henry's		Bob's	
	Promise	Threat	Promise	Threat
<i>If bike then help</i>	given	9	-	-
<i>If no bike then no help</i>	8	given	1	2
<i>If help then bike</i>	2	-	given	8
<i>If no help then no bike</i>	-	1	9	given

from the three others known from the formulation task. The results are presented in Table 2. As predicted, participants preferred the complementary conditional, which leaves the order of the actions the same, over the reversed one (85.0% vs. 12.5%, aggregated over all tasks, $\chi^2(1, n = 39) = 21.6; p < 0.001$).

(3) **Sequence task:** In the third task, the participants had to decide on the order of the actions once the conditional inducement had been made. It was expected that the addressee would decide first whether he is willing to cooperate. Without exception, all participants (100%) answered the sequence question according to this prediction. If Henry made the inducement then Bob decides first whether he lends out his bike, and vice versa. Thus, changing roles reversed the typical action sequence.

Altogether, the results of the first three tasks corroborate the predicted speaker-addressee asymmetry.

(4) **Emotion task:** After the introduction of the conditional inducement in the context story, the emotion task mentioned that the addressee *cooperated* and fulfilled the speaker's goal (S+). Participants had then to decide (i) what the *speaker* has to do in order to keep versus not to keep 'the rule', and (ii) which feeling the *addressee* will have afterwards. Three critical emotions (relief, joy, and anger) were given together with four distractors in a multiple-choice format and participants were instructed to choose the most appropriate one.

(i) To keep the rule means that, given that the addressee cooperated before (S+), the speaker will also cooperate (A+). Cooperation corresponds to the MP inference in the case of a conditional promise '*If P [S+], then Q [A+]*', but to the NA inference in the case of a threat '*If P [S-], then Q [A-]*'. Not keeping the rule means reacting defectively towards the addressee (A-) *even though* the addressee fulfilled the speaker's goal (S+). In the case of a promise, defection violates the conditional statement itself ('P and not-Q'). In the case of a conditional threat, however, defection corresponds to '*not-P and Q*' and violates the complementary conditional. The results show that the participants had a clear understanding of these regularities: Asked what the speaker has to do in order to "keep the rule", all persons (100.0%) choose the MP-option given a promise, but the NA-option (95.0%) given a threat (aggregated over both

Table 3: Attributed emotional reactions of the addressee on keeping vs. not keeping a promise/threat.

Emotion	Keeping		Not Keeping	
	Promise	Threat	Promise	Threat
Relief (+)	5	10	-	-
Joy (+)	15	5	-	1
Anger (-)	-	3	19	19
Others (-)	-	3	3	1

The frequencies do not add up to 20 in each column because four persons marked two emotions.

role versions). Correspondingly, all persons (100.0%) answered that not keeping a promise corresponds to 'P and not-Q', while again 95.0% chose the complementary category 'not-P and Q' in the case of a threat.

(ii) How does the addressee react emotionally in these cases? Table 3 lists positive and negative emotions (+/-) aggregated over both role versions. The answers are in line with the predictions from appraisal theories: If the speaker keeps the rule then the addressee is said to feel a *positive* emotion (85.4% positive vs. 14.6% negative); otherwise a *negative* emotion results (2.3% positive vs. 97.7% negative; $\chi^2(1, n = 84) = 59.1; p < 0.001$). In the latter case, the addressee was uniformly said to feel *angry*, whereas in the former case different emotions were associated with the two speech acts: Keeping the promise mostly resulted in *joy* (75% joy vs. 25% relief) while in the case of a threat *relief* predominates (23.8% joy vs. 47.6% relief; $\chi^2(1, n = 35) = 6.08; p = 0.014$); on three occasions the addressee was even said to feel *angry*. This may be the result of having been forced to cooperate by a threat. Whether these differences reflect differences between the speech acts or between the incentives (lending out one's bike vs. giving help with the other's homework) is open to further analyses.

Part II: Assessing Deontic Inferences

Part II aimed to test the hypothesis that the deontic interpretation of a conditional threat follows the interpretation of the corresponding complementary promise: If the addressee cooperates, then the speaker is obliged to cooperate; otherwise he is not. Thus, the deontic inferences from complementary promises and threats need to be compared. This was done in two content versions (mutual lending vs. mutual destruction).

The scenarios of mutual lending stated that Peter would like to borrow Corinna's comic book. He tries to achieve this goal either by a promise ("If you lend me your comic book, then I will lend you my computer game") or by a complementary threat ("If you do not lend me your comic book, then I will not lend you my computer game"). The mutual destruction scenario concerned two quarreling children. Sarah is about to smash

George's Lego car. George would like to prevent Sarah from smashing his car. George knows that Sarah has set up her Playmobil farm. Again, George tries to achieve this goal either by a threat ("If you smash my car, then I will smash your farm") or by a complementary promise ("If you do not smash my car, then I will not smash your farm"). Altogether, four context stories were used. Each was followed by four tasks that asked for deontic inferences about the speaker's action after the addressee had already cooperated versus the speaker's action after he had not.

Task 1+2: The addressee cooperated: The first two tasks supplemented the context story with the information that the addressee fulfilled the speaker's goal (i.e., Corinna lent her comic book to Peter, and in the other scenario, Sarah did not smash George's Lego car). The first task required participants to decide whether the addressee's cooperation implies an obligation for the speaker to cooperate also. The second task asked whether the speaker is permitted to cooperate. It was expected that the deontic interpretation of the threat would follow the one of the complementary promise in both content versions equally: The speaker is *obliged* to cooperate (i.e., Peter must lend out his computer game while, in the other scenario, George must refrain from smashing Sarah's Playmobil farm), and the speaker is *permitted* to do so.

Task 3+4: The addressee did not cooperate: The other two tasks stated that the addressee did not fulfill the speaker's goal (i.e., Corinna did not lend out her comic book, while Sarah smashed George's Lego car). Again, the participants had to decide whether the speaker is obliged to cooperate and whether he is permitted to do so. This time it was predicted that – independent from the speech act and the content – *no obligation* would arise for the speaker (i.e., Peter need not lend out his computer game and George need not refrain from smashing Sarah's Playmobil farm), but again the speaker is *permitted* to cooperate.

To test the hypothesis that the deontic interpretation of conditional threats is equivalent to the interpretation of the complementary promises, a log-linear analysis (Kennedy, 1992) with two independent variables (speech act and content) was performed for each task. The analyses corroborated the hypotheses: neither the factor *speech act* nor the factor *content* significantly contributed to the data. Both factors could be removed from the analyses without losing the fit of the resulting log-linear model (for each analysis: $G^2 < 10.5$, $df = 6$, $p > 0.10$). It is thus justifiable to aggregate the data of each task over the four groups.

The aggregated results are shown in Table 4. Most participants drew the deontic inferences that were predicted from the explicit (or implicit) conditional promise: An obligation arises for the speaker only if the addressee A cooperates (67.5% *obligation* vs. 0% *no obligation*), but not if A does not cooperate (10.0% *obligation* vs. 77.5% *no obligation*; $\chi^2(1, n = 62) = 47.8; p < 0.001$). Independent from the fact whether the

Table 4: Percentages of deontic inferences aggregated over content versions and speech acts ($N = 40$ in each condition; expected inferences are bold-faced).

	The addressee A ...	
	cooperated	did not cooperate
<i>Obligation: Must the speaker S cooperate?</i>		
obligation	67.5	10.0
no obligation	0.0	77.5
undecidable	32.5	12.5
<i>Permitted: May the speaker S cooperate?</i>		
permitted	67.5	50.0
not permitted	5.0	22.5
undecidable	27.5	27.5

addressee cooperated or not, the speaker was said to be permitted to cooperate (58.8% *permitted* compared to 20.6% *not permitted* and *undecidable* answers on average; $\chi^2(1, n = 80) = 23.3; p < 0.001$).

Summary and Discussion

The results of both experimental parts show a clear and consistent picture that strongly corroborates the predictions from the multi-level analysis.

Conditional inducements are specifically formulated depending on the motivational background and the intended speech act. Thus, conditional promises and threats cannot simply be reversed. This is due to the speaker-addressee-asymmetry: The canonical conditional and its reversal correspond to speech acts of different persons, they have different implications and are associated with complementary action sequences.

It could further be shown that the deontic interpretation of conditional threats is not derived from the conditional formulation, but from the implicit complementary promise. No matter whether a person uses a promise or a threat to pursue his or her goal, there is an obligation to cooperate if the addressee fulfills this goal.

Finally, conditional inducements concern individual goals, actions, and incentives, and are thus highly emotional speech acts. The addressee was said to feel *joy* or *relief* when the speaker kept "the rule" and cooperated, whereas the addressee reacted *angrily* when the speaker broke the rule. This is in line with predictions from appraisal theories of emotion (e.g., Lazarus, 1991; Roseman et al., 1996). Several questions, however, are open to further analyses: Which emotional reactions are associated with other possible action sequences? How does the content of the inducements (e.g., reciprocal exchange or mutual destruction) affect the emotional reactions? Further experiments are needed to answer these questions.

In short, the multi-level analysis of conditional inducements brings together motivation, linguistics, pragmatics, deontic considerations, and emotions. It thereby overcomes the limitations of a purely truth functional analysis often found in reasoning studies.

Combining Simplicity and Likelihood in Language and Music

Rens Bod (rens@science.uva.nl)

Cognitive Science Center Amsterdam, University of Amsterdam
Nieuwe Achtergracht 166, Amsterdam, The Netherlands

Abstract

It is widely accepted that the human cognitive system organizes perceptual input into complex hierarchical descriptions which can be represented by tree structures. Tree structures have been used to describe linguistic, musical and visual perception. In this paper, we will investigate whether there exists an underlying model that governs perceptual organization in general. Our key idea is that the cognitive system strives for the simplest structure (the "simplicity principle"), but in doing so it is biased by the likelihood of previous experiences (the "likelihood principle"). We will present a model which combines these two principles by balancing the notion of most likely tree with the notion of shortest derivation. Experiments with linguistic and musical benchmarks (Penn Treebank and Essen Folksong Collection) show that such a combination outperforms models that are based on either simplicity or likelihood alone.

Introduction

It is widely accepted that the human cognitive system organizes perceptual input into complex, hierarchical descriptions which can be represented by tree structures. Tree structures have been used to describe linguistic perception (e.g. Chomsky 1965), musical perception (e.g. Lerdahl & Jackendoff 1983) and visual perception (e.g. Marr 1982). Yet, there seems to be little or no work which emphasizes the commonalities between these different forms of perception and which searches for a general, underlying mechanism which governs all perceptual organization (cf. Leyton 2001). This paper aims to study exactly that question: acknowledging the differences between linguistic, musical and visual information, is there a general, unifying model which can predict the perceived tree structure for sensory input? In studying this question, we will use a strongly empirical methodology: any model that we might hypothesize will be tested against benchmarks such as the linguistically annotated Penn Treebank (Marcus et al. 1993) and the musically annotated Essen Folksong Collection (Schaffrath 1995). While we will argue for a unified model of language, music and vision, we will carry out experiments only with linguistic and musical benchmarks, since no benchmarks of visual tree structures are currently available, to the best of our knowledge.

Figure 1 gives three simple examples of linguistic, musical and visual input with their corresponding tree structures given below.

Thus a tree structure describes how parts of the input combine into constituents and how these constituents combine into a representation for the whole input. Note

that the linguistic tree structure is labeled with syntactic categories, whereas the musical and visual tree structures are unlabeled. This is because in language there are syntactic constraints on how words can be combined into larger constituents, while in music (and to a lesser extent in vision) there are no such restrictions: in principle any note may be combined with any other note.

List the sales of products in 1973

Figure 1: Examples of tree structures.

Apart from these differences, there is also a fundamental commonality: the perceptual input undergoes a process of hierarchical structuring which is not found in the input itself. The main problem is thus: how can we derive the perceived tree structure for a given input? That this problem is not trivial may be illustrated by the fact that the inputs above can also be assigned the following, alternative tree structures in figure 2.

Figure 2: Alternative tree structures for figure 1.

These alternative structures are possible in that they *can* be perceived. But while the alternative tree structures are all possible, they are not plausible: they do not correspond to the structures that are actually perceived by the human perceptual system.

The phenomenon that the same input may be assigned different structural organizations is known as the *ambiguity problem*. This problem is one of the hardest problems in modeling human perception. Even in language, where a phrase-structure grammar may specify which words can be combined into constituents, the ambiguity problem is notoriously hard. Charniak (1997: 37) argues that almost every sentence from the Wall Street Journal has many, often more than one million different parse trees. The ambiguity problem for musical and visual input is even harder. Talking about rhythm perception in music, Longuet-Higgins and Lee (1987) note that "Any given sequence of note values is in principle infinitely ambiguous, but this ambiguity is seldom apparent to the listener."

Two principles: likelihood and simplicity

How can we predict from the set of all possible tree structures the tree that is actually perceived by the human cognitive system? In the field of visual perception, two competing principles have traditionally been proposed to govern perceptual organization. The first, initiated by Helmholtz (1910), advocates the *likelihood principle*: sensory input will be organized into the most probable organization. The second, initiated by Wertheimer (1923) and developed by other Gestalt psychologists, advocates the *simplicity principle*: the perceptual system is viewed as finding the simplest perceptual organization (see Chater 1999 or Van der Helm 2000 for an overview). These two principles are not only relevant for visual perception, but also for linguistic and musical perception. In the following, we briefly discuss these principles for each modality, after which we go into the question of how the two principles can be integrated.

Likelihood

The likelihood principle is particularly influential in the field of natural language processing (see Manning and Schütze 1999, for a review). In this field, the most appropriate tree structure of a sentence is assumed to be its most likely structure. The likelihood of a tree is usually computed from the probabilities of its parts (e.g. phrase-structure rules) taken from a large annotated language corpus (a *treebank*). A widely used treebank for testing and comparing probabilistic natural language parsers is the Penn Wall Street Journal Treebank (Marcus et al. 1993). State-of-the-art probabilistic parsers such as Collins

(2000), Charniak (2000) and Bod (2001a) obtain around 90% precision and recall on the Wall Street Journal. Also in the field of psycholinguistics, the likelihood principle is widely used: Jurafsky (1996), Crocker and Brantz (2000) and Hale (2001) are examples of psycholinguistically inspired probabilistic parsers.

The likelihood principle has also been applied to musical perception, e.g. in Raphael (1999) and Bod (2001b/c). As in probabilistic natural language processing, the most probable musical tree structure can be computed from the probabilities of rules or fragments taken from a large annotated musical corpus, for instance from the Essen Folksong Collection (Bod 2001b).

In visual perception psychology and vision science, there has recently been a resurgence of interest in probabilistic models (e.g. Hoffman 1998; Kersten 1999). Mumford (1999) has seen fit to declare the Dawning of Stochasticity.

Simplicity

The simplicity principle has a long tradition in the field of visual perception psychology (e.g. Restle 1970; Leeuwenberg 1971; Simon 1972; Buffart et al. 1983; van der Helm 2000). In this field, a visual pattern is formalized as a constituent structure by means of a "visual coding language" based on primitive elements such as line segments and angles. Perception is described as the process of selecting the simplest structure corresponding to the "shortest encoding" of a visual pattern.

The notion of simplicity has also been applied to musical perception. Collard et al. (1981) use the coding language of Leeuwenberg (1971) to predict the metrical structure for four preludes from Bach's *Well-Tempered Clavier*. More well-known in musical perception is the theory proposed by Lerdahl and Jackendoff (1983) who use a system of preference rules based on the Gestalt-preferences identified by Wertheimer (1923), and which can therefore also be seen as an embodiment of the simplicity principle.

Notions of simplicity also exist in language processing (e.g. Frazier 1978; Gorrell 1995; Osborne 2000). Bod (2000a) defines the simplest tree structure of a sentence as the structure generated by the smallest number of subtrees from a given treebank.

Combining the two principles

The key idea of the current paper is that both principles play a role in perceptual organization: the simplicity principle as a general cognitive preference for economy, and the likelihood principle as a probabilistic bias due to previous perceptual experiences. Informally stated, our working hypothesis is that the human cognitive system strives for maximal economy (the simplest structure), but that in doing so it is biased by the likelihood of previous experiences (in the last section we will discuss some other combinations of simplicity and likelihood that have been proposed). To formally instantiate our working hypothesis, we need a parsing model to start with which can incorporate these principles. In principle any parsing model might do, as long as it can assign tree structures to

perceptual input according to some criterion. For the current paper, we have chosen to start with the Data-Oriented Parsing model (Bod 1998) because (1) it has several other models as special cases, such as context-free parsing models and lexicalized models, and (2) it has been quite successful in predicting tree structures for both linguistic input (Bod 2001a) and musical input (Bod 2001b).

The basic idea of DOP is that it learns a grammar by extracting subtrees from a given treebank and uses these subtrees to analyze fresh input. Suppose we are given the following linguistic treebank of only two trees (we will come back to musical treebanks in the next section),

Figure 3: An example treebank

then the DOP model can parse a new sentence, e.g. *She saw the dress with the telescope*, by combining subtrees from this treebank by means of a *node-substitution operation* (indicated as \circ):

Figure 4: Parsing a sentence by combining subtrees

Thus the node-substitution operation combines two subtrees by substituting the second subtree on the leftmost nonterminal leaf node of the first subtree. Since DOP uses subtrees of arbitrary size, there are typically several derivations, involving different subtrees, that produce the same parse tree; for instance:

Figure 5: Different derivation producing same tree.

The more interesting case occurs when there are different derivations that produce *different* parse trees. This happens when a sentence is structurally ambiguous; for

example, DOP also produces the following alternative parse tree for *She saw the dress with the telescope*:

Figure 6: Different derivation producing different tree.

The original DOP model in Bod (1993) uses the likelihood principle to predict the perceived tree structure. We will refer to this model as *Likelihood-DOP*. Likelihood-DOP selects the most likely tree structure from among all possible tree structures on the basis of the probabilities of its subtrees. The probability of a subtree t is estimated as the number of occurrences of t seen in the corpus, divided by the total number of occurrences of corpus-subtrees that have the same root label as t . The probability of a derivation is computed as the product of the probabilities of the subtrees involved in it. Finally, the probability of a parse tree is equal to the sum of the probabilities of all distinct derivations that produce that tree. In Bod (2001a) and Goodman (2002), efficient algorithms are given that compute for an input string the most probable parse tree.

Likelihood-DOP does not do justice to the preference humans display for the simplest structure, e.g. the one that is generated by the shortest derivation consisting of the fewest subtrees. This is what we will call *Simplicity-DOP*. Instead of producing the most probable parse tree for an input, Simplicity-DOP produces the parse tree generated by the fewest corpus-subtrees, independent of the probabilities of these subtrees. For example, given the corpus in Figure 3, the simplest parse tree for *She saw the dress with the telescope* according to Simplicity-DOP is given in Figure 5, since that parse tree can be generated by a derivation of only two corpus-subtrees, while the parse tree in Figure 6 (and any other parse tree) needs at least three corpus-subtrees to be generated. In Bod (2000a) it is shown how the shortest derivation can be efficiently computed by means of a best-first bottom-up chart parsing algorithm. Simplicity-DOP obtains quite impressive results on the WSJ, though its results are lower than Likelihood-DOP (Bod 2000a). Yet, the set of correctly predicted parse trees of Simplicity-DOP is *not* a subset of the set of correctly predicted parse trees of Likelihood-DOP. This suggests that we may expect an accuracy improvement if simplicity and likelihood are combined into a new model, which we will call *Combined-DOP*.

The underlying idea of Combined-DOP is that the human perceptual system searches for the shortest derivation (i.e. the simplest tree structure), but that in doing so it is biased by the "weights" of the subtrees. The length of a derivation is then not defined simply as the sum of the derivation steps (as in Simplicity-DOP), but as the sum of the weights of these steps, where a low weight should be seen as an easy step and a heavy weight as a

difficult step. As a measure for weight of a subtree, we have worked out various proposals that were experimentally tested over the last few years. Most of these proposals have been reported in the literature (e.g. Bod 2000a; Cormons 1999). The best measure for subtree weight so far is based on the *rank* of a subtree. First, all subtrees are grouped with respect to their root label. Next, for each root label the weight of a subtree is defined as its rank in the frequency ordering in the corpus. Thus, the most frequent subtree in each ordering gets a weight of 1, the second most frequent subtree gets a weight of 2, etc. The weight of a derivation is then defined as the sum of the weights of the subtrees in the derivation. The derivation with the lowest weight is taken as the "best" derivation producing the perceived parse tree. Thus, the best derivation is not determined by the smallest sum of the subtrees (as in Simplicity-DOP), but by the smallest sum of the *weights* of the subtrees.

We performed one additional adjustment to the weight of a subtree. This adjustment consists in a smoothing technique which averages the weight of a subtree by the weights of its own sub-subtrees. That is, instead of taking only the rank of a subtree as its weight, we compute the weight of a subtree as the (arithmetic) mean of the weights of all its sub-subtrees (including the subtree itself). The effect of this smoothing technique is that it redresses a very low-frequency subtree if it contains high-frequency sub-subtrees.

The Test Domains

Our linguistic test domain consists of sections 02-21 of the Wall Street Journal portion of the Penn Treebank, which contains approx. 40,000 phrase-structure trees. Since the Penn Treebank has been extensively described in the literature (e.g. Marcus et al. 1993; Manning & Schütze 1999), we will not go into it any further here.

The musical test domain consists of the European folksongs in the Essen Folksong Collection (Schaffrath 1995), which correspond to approx. 6,200 musical grouping structures. The Essen Folksong Collection has been previously used by Bod (2001b) and Temperley (2001) to test their musical parsers. The musical coding language used in the Essen Folksong Collection is based on the Essen Associative Code (ESAC). The pitch encodings in ESAC resemble "solfege": scale degree numbers are used to replace the movable syllables "do", "re", "mi", etc. Thus 1 corresponds to "do", 2 corresponds to "re", etc. Chromatic alterations are represented by adding either a "#" or a "b" after the number. The plus "+" and minus "-" signs are added before the number if a note falls resp. above or below the principle octave (thus -1, 1 and +1 refer al to "do", but on different octaves). Duration is represented by adding a period or an underscore after the number. A period (".") increases duration by 50% and an underscore ("_") increases duration by 100%; more than one underscore may be added after each number. If a number has no duration indicator, its duration corresponds to the smallest value. A pause is represented by 0, possibly followed by duration indicators. No loudness or timbre indicators are used in ESAC. The only extra information we (automatically) added to the grouping structures in the Essen Folksong

Collection consists of the label "S" for each top node of each whole song and the label "P" for each underlying phrase. In this way, we obtained conventional parse trees that can directly be used by our DOP models to parse new input strings (see also Bod 2001b). The Essen Folksong Collection is freely available via <http://www.esac-data.org>.

As mentioned in the introduction, no visual treebank is currently available, to the best of our knowledge. We are currently developing a treebank of analyzed architectural plans, and will report on experiments with that treebank in due time.

Experimental Evaluation

To evaluate our DOP models, we used the *blind testing* method which dictates that a treebank be randomly divided into a training set and a test set, where the strings from the test set are parsed by means of the subtrees from the training set. We applied the PARSEVAL metrics of *precision* and *recall* to compare a proposed parse tree *P* with the corresponding correct test set parse tree *T* (see Black et al. 1991):

$$\text{Precision} = \frac{\# \text{ correct constituents in } P}{\# \text{ constituents in } P} \quad \text{Recall} = \frac{\# \text{ correct constituents in } P}{\# \text{ constituents in } T}$$

A constituent in *P* is "correct" if there exists a constituent in *T* of the same label that spans the same elements (i.e. words or notes). To balance precision and recall into a single measure, we will employ the widely used F-score: $F\text{-score} = 2 * \text{Precision} * \text{Recall} / (\text{Precision} + \text{Recall})$.

We will use this F-score to quantitatively evaluate our models on the Wall Street Journal and the Essen Folksong treebanks. We divided both treebanks into 10 training/test set splits, where 90% of the trees was used for training and 10% for testing. These splits were random, except for one constraint: that all the primitive elements (i.e. words and notes) in the test set also occurred in the training set. In this way, we did not have to worry about unknown words or unknown notes (the latter being actually inexistent for our musical treebank). Although there are various statistical ways to cope with unknown words, we wanted to rule out this problem as it might obscure our comparison.

In our experiments we were first of all interested in comparing the three DOP models (Likelihood-DOP, Simplicity-DOP and Combined-DOP) on the two domains. For computational reasons, we limited the maximum size of the subtrees to depth 14, as in Bod (2001a). Table 1 shows the average F-scores for each of the models.

Table 1: F-scores obtained by the three DOP models

	Likelihood-DOP	Simplicity-DOP	Combined-DOP
Language	90.4%	88.1%	91.7%
Music	86.0%	84.3%	86.9%

The table shows that Likelihood-DOP outperforms Simplicity-DOP, but that Combined-DOP outperforms Likelihood-DOP. According to paired *t*-testing, the

improvement of Combined-DOP over Likelihood-DOP was statistically significant both for language ($p < .0001$) and for music ($p < .04$).

We also performed a series of experiments where we restricted the size of the subtrees. Recall that by restricting the subtrees to depth 1, Likelihood-DOP becomes equivalent to a probabilistic context-free grammar, while Simplicity-DOP would just return the smallest possible tree structure. While Likelihood-DOP still obtained relatively good results at depth 1 for both language and music (resp. 75.1% and 76.6%), Simplicity-DOP scored very badly for language (22.5%) though still reasonably for music (70.0%). Interestingly, Combined-DOP scored worse than Likelihood-DOP at depth 1 (resp. 68.2% vs. 74.6%). Only after subtree depth 6 for language and subtree depth 2 for music, Combined-DOP outperformed Likelihood-DOP. The highest F-scores were obtained with the "unrestricted" subtrees (in table 1).

Elsewhere we have shown that virtually *any* constraint on the subtrees results in an accuracy decrease (Bod 2001a/b). This is because in language, almost any relation between words (including between so-called non-headwords) can be important for predicting the perceived parse tree of a sentence. The same counts for music, where there is a continuity between "jump-phrases" and "non-jump-phrases", which can only be captured by large subtrees (see Bod 2001b/c for an extensive discussion).

Discussion: Other Combinations of Simplicity and Likelihood

We have seen that our combination of simplicity and likelihood is quite rewarding for linguistic and musical perception, suggesting a deep parallel between the two modalities. Yet, we should raise the question whether a model which massively stores and re-uses previously perceived structures has any cognitive plausibility. Interestingly, there is quite some evidence that people store various kinds of previously heard fragments, both in music (Saffran et al. 2000) and language (Jurafsky 2002). But do people store fragments of *arbitrary* size, as proposed by DOP? In his overview article, Jurafsky (2002) reports on a large body of psycholinguistic evidence showing that people not only store lexical items and bigrams, but also frequent phrases and even whole sentences. For the case of sentences, people not only store idiomatic sentences, but also "regular" high-frequency sentences. Thus, at least for language it seems that humans store fragments of arbitrary size provided that these fragments have a certain minimal frequency. However, there seems to be no evidence that people store *all* fragments they hear, as suggested by DOP. Only high-frequency fragments seem to be memorized. However, if the human perceptual faculty needs to *learn* which fragments will be stored, it will initially need to keep track of all fragments (with the possibility of forgetting them) otherwise frequencies can never accumulate. This results in a model which continuously and incrementally updates its fragment memory given new input, which is in correspondence with the DOP approach.

There have been other proposals for integrating or reconciling the principles of simplicity and likelihood. Chater (1999) argues that the principles are identical in

the context of Kolmogorov's complexity theory (Kolmogorov 1965). And in the context of Information Theory the simplicity principle can be defined in terms of bit length, such that maximizing likelihood corresponds to minimizing bit length (cf. Rissanen 1978). First note that the likelihood principle aims at maximizing the probability of a structure given an input, $p(\text{structure} | \text{input})$. Next, define the simplicity principle as minimizing the informatic-theoretical notion of bit length, which is the (negative) logarithm of the probability of a structure given an input: $-\log p(\text{structure} | \text{input})$. Now it is easy to see that maximizing $p(\text{structure} | \text{input})$ leads to the same structure as minimizing $-\log p(\text{structure} | \text{input})$. Thus the two principles lead to the same result.

However, in the context of DOP we defined the simplest structure as the one generated by the shortest derivation consisting of the smallest number of subtrees (reflecting the smallest number of steps needed to parse an input). And this notion of simplest structure is provably different from the most probable structure given an input. Although it is possible to redefine our notion of simplest structure in terms of bit length, it would not lead to any new model, and to no improved result. By conceptually separating between simplicity and likelihood in DOP and by combining them in a novel way, we have shown that an improved model can be obtained.

What we have not done in this paper is to isolate the perceptual properties for which *no* prior expectations are needed. Even Simplicity-DOP, albeit non-probabilistic, is heavily based on previously perceived data. It is very likely that there are perceptual grouping properties for which no prior expectations are necessary. DOP does not contribute to the discovery of such properties, but it does neither neglect them, as they are implicit in the treebank. Bod (2001b) shows that Wertheimer's Gestalt principles are reflected in about 85% of the phrases in the Essen Folksong Collection (where phrases have boundaries that fall on large time or pitch intervals). DOP automatically takes these principles into account by subtrees that contain such phrases, but DOP also takes into account phrases whose boundaries do *not* fall on large intervals (so-called "jump-phrases"). By using all subtrees, DOP mimics the preferences humans have used in analyzing the perceptual data, whatever these preferences may have been.

Mental Models Theory and Anaphora

Guido Boella and Leonardo Lesmo

Dipartimento di Informatica and Centro di Scienza Cognitiva

Università di Torino

email: {guido, lesmo}@di.unito.it

Abstract

We argue that anaphora cannot be resolved at the level of the formal language representing meaning, but, rather, by making direct reference to the *extension* of the sentences. Johnson-Laird's mental models theory provide the tool for coping with extensional representations in a cognitively plausible way.

Introduction

Anaphoric expressions are traditionally viewed as substitutes for more complex linguistic expressions which have already occurred earlier in the text. Anaphora has proven difficult to analyze at a purely syntactic level, so that structural approaches like DRT [10] or semantic ones like Dynamic Semantics [4] cope with this problem by enriching the formal language used to build or to represent the meaning of sentences.

We believe that the limit of these approaches is that they have chosen the wrong level of representation for dealing with anaphora: we will show that it is necessary to make direct reference to *extensional* representations of meaning. In particular, the representation of the context should put at disposal the elements of the situation, which anaphors can refer to, instead of hiding them behind quantified expressions.

However, extensions can possibly be infinite or too large to be dealt with directly. But there is a proposal which uses extensional representations of finite and limited size, and which has been shown to be cognitively plausible, i.e., the *mental models theory* of [9]. Johnson-Laird has used mental models in order to explain how people reason without having to resort to formal logic. Inferences are performed by manipulating extensional representations of sentences which are composed of a finite number of elements and relations: "a mental model represents the extension of an assertion, i.e., the situation it describes, and the recursive machinery for revising the model represents the intension of the assertion, i.e., the set of all possible situations it describes." (p.100)

In [8]'s words: "mental models theory is a psychological theory of language processing and reasoning. The theory provides a framework within which more detailed accounts of the component processes of comprehension [...] such as anaphora interpretation [...] and reasoning can be developed, [...] Mental models theory assumes

that comprehension results in the construction of representations of situations in the real world [...] These models are finite and computable, and they are constructed incrementally, with the model so far acting as part of the context for interpreting the current text. (p.20)

A simple preliminary example illustrates our solution. In the following sentences, the acceptability is guaranteed just for the pair where the (intended) antecedent (a donkey) and the pronoun (*they*) do not agree in their syntactic number:

(1) *Every farmer owns a donkey. *It is pink.*

(2) *Every farmer owns a donkey. They are pink.*

When the second sentence in each discourse is interpreted, it produces a mental model which must be integrated with the preceding one: a referent must be found for the anaphoric expressions. If we examine in the Figure below how the first sentences of the two pairs are represented in mental models theory, we see that the problem is easily solved.

The mental model contains a finite number of tokens (placeholders for individuals,

here farmers *f* and donkeys *d*) and relations among tokens (the arrows labeled with *own*). Given the model above, which donkey, out of the represented ones, can we relate to the singular *it*, appearing in the second sentence of (1)? The problem of identifying the referent appears to be the same as in: (3) *I have three sisters. *She is blonde* where we have to choose one referent out of three candidates. One is given no (or not enough) information to identify the antecedent (among the three sisters) denoted by *she*. On the contrary, the *they* pronoun in (2) can be interpreted as referring to the set of donkeys appearing in the model, due to its plural syntactic number.

The mental model building algorithm

First of all, the sentence undergoes a syntactic and semantic interpretation process that produces a semantic network (see [6], [11] and [2] for details on the network representation). Then, following the proposal by [9], that "a propositional representation can be used as the input to a procedural semantics that constructs mental mod-

els", a mental model representing the meaning of the sentence is built.

The network representation

For the present purposes, we will describe briefly only the mechanism of Distributivity Ambiguity Spaces (DAS) which deals with the possible distributive readings of an NP (see [11] for details).

The nodes of the network can be simple or DASs. The latter correspond to plural NPs, and they were introduced to deal with the distinction between *collective* and *distributive* readings of predicates: each DAS includes two subnodes *Set* and *Indiv*.

In case of (4) *Three men lifted three tables*, if the subject NP is given a reading as a set, the men are seen as being jointly involved in the act of lifting tables. Viceversa in the individual reading of the subject, each man executed a separate lifting act. If the tables are interpreted as a set too, they were lifted all together (perhaps they were stacked). On the contrary, if they are interpreted as individuals, the men lifted them one at a time. The four combinations of *Set*, *Indiv* readings for the subject and the object do not cover all possibilities. In fact, it may happen that, for the *Indiv* reading of the subject, there exist just three tables, and each man lifted one of them (three individual lifting acts); or that each man lifted three tables (possibly, but not necessarily, the same three tables; 9 different tables could be involved), so that nine individual lifting acts have been executed. Or, in the *Set* reading of the object, the three men lifted three different stacks of tables (so, we have two more readings, for a total of 6). The extra readings (see Figure 1) are accounted for by means of a mechanism other than the DAS described above (but independently motivated, see [11]), i.e. by the presence of DEP-ON (dependent on) arcs. They are similar to Skolem functions in first order logic, and were introduced for representing quantifier scoping. Each node which is not universally quantified can be specified to be dependent on another 'plural' node. For instance, in *Every farmer owns a donkey*, the most natural reading is where each farmer owns a different donkey, so that the particular donkey 'depends on' the particular farmer.

Mental models

In order to use a more unambiguous version of the framework with respect to the 'diagrammatic' original version of [9], we refer to the formalization of mental models provided by [1].

According to [1], a model is triple $\langle T, R, A \rangle$, where T is a (non-empty) bi-dimensional matrix of tokens, R is a set of relations on T , and A is a set of annotations. For dealing with some interpretations, more than one model can be required.

A token is either a model or an element. An element is a pair $\langle S, A \rangle$ where S is a symbol from a given vocabulary and A is a set of annotations; the vocabulary consists of named individual entities (John for the proper name *John*) and generic entities belonging to some category (c_i for cars, f_i for farmers, etc.).

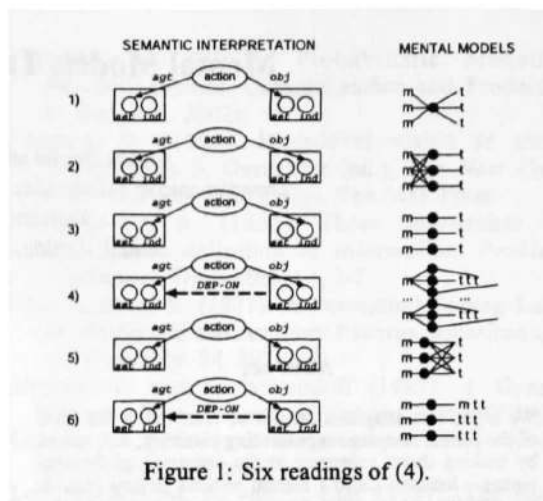

Figure 1: Six readings of (4).

A relation is an ordered sequence $\langle r, x_1, \dots, x_n, A \rangle$ where r is a relation symbol, x_1, \dots, x_n are tokens in T and A is a set of annotations. Annotations are "the propositional enrichment of the analogical structure of the model" [1]. In particular, the "not" annotation applies to any feature of the models. For models and relations, a negation means that they are not the case; for entities, that they are absent in a model. The "..." annotation means that the model can be further extended.

[1] consider relations such as 'above', 'faster' and two special relations "connected with" (CW) and "never connected with" (NCW). The CW relation forms an individual by connecting two of its properties. The NCW one states that two properties cannot hold for the same individual. Usually the two relations are used to represent the meaning of, respectively, *all humans are mortals* and *most lawyers are not poor*. With respect to [1]'s framework, we introduce an extension for what concerns the NCW relation. In fact, NCW is originally meant to apply only to unary predicates such as being humans or mortal. We introduce a version of the NCW relation relativized to a predicate rel , $NCW(rel)$. In fact, the "not" annotation of a relation means that the relation is not true of the given entities involved in the relation. In $\langle \text{faster, john, bill, \{not\}} \rangle$, the negation does not concern the existence or not of the two individuals John and Bill, which are introduced as existing entities. But this is not sufficient to represent the meaning of a sentence like *John does not have a car*: since the phrase *a car* inside a negation does not introduce or refer to an entity in the model, the meaning of the sentence cannot be represented by the negation of the 'have' relation: in fact, a relation as $\langle \text{have, john, } c_1, \{\text{not}\} \rangle$ does not express the fact that from the model it is not possible to infer that there is a car. Rather, this annotated relation expresses the fact that there is a car in the model and John is not its owner.

What we need is something similar to the interpretation of the sentence *no lawyer is a crook* from which is not possible to infer that there is some crook in the model. The model of this sentence in [1] is not represented by a negation of some predicate 'is' but with the NCW rela-

tion discussed above: $\langle \text{NCW}, \text{lawyer}_i, \text{crook}_i \rangle$. Analogously, for interpreting *John does not have a car* we introduce a NCW(have) predicate, which not only expresses the negation of the "have" predicate, but which also does not assert the existence of any car (see the Figure below).

In $\langle \text{NCW}(\text{have}), \text{john}, c_1, \emptyset \rangle$, cars, as in $\langle \text{NCW}, \text{bicycle}_i, c_i, \emptyset \rangle$ (*no bicycle is a car*), are kept separate from the other entities in the model: they cannot play the role of antecedents of pronouns.

For what concerns the treatment of logical connectives, we stick to the proposal of [1].

From the network to the mental model

The model constructing procedure takes as input an existing mental model (representing the context) and the network representation of the new sentence (still associated with the syntactic tree): the newly constructed model is *integrated* with the existing ones by overlapping identical tokens and finding referent tokens for anaphoric expressions.

The process starts from the non-dependent entity nodes of the network which derive from the interpretation of NPs (i.e. NPs without exiting DEP-ON arcs), and proceeds with the other NPs, according to the (partial) order imposed by (reversed) DEP-ON arcs. After that, all co-references are solved. For instance, in (5) *Every farmer who owns a donkey beats it, every farmer* is processed first, then *a donkey* and, the pronoun *it* which depend on the subject NP.

More precisely, given a context M composed by a model $\langle T, R, A \rangle$, we have that a network W is interpreted as a new model $\langle T', R', A' \rangle$, in the following way:

1. Each non-dependent entity node in the network W deriving from the interpretation of an NP is treated separately:

(a) If the entity node represents an NP which is a proper noun (e.g., *John*), an individual token (e.g., *john*) is introduced in the matrix T of the model M ; if that token is already present in the model, the two tokens are identified.

(b) If the NP is a quantified Noun (e.g., *every farmer*), a set of distinct tokens $F = \{x_1, \dots, x_n\}$ representing the denotation of the noun is added to the context matrix T ; depending on the quantifier Q , a subset of them, $Q(F)$, will be selected for linking to other tokens by the relation where the NP occurs as an argument (selecting the whole set in case of *every* and *all*, a proportioned subset of it in case of *most*, etc). The annotation A of the model can be augmented with a "...", since, depending on the quantifier, more tokens could be added to the matrix T or the set $Q(F)$ could be revised (e.g., if $Q = \text{"some"} | Q(F) |$ could be initially 2 or 3, but it can be increased in case of necessity, as in the standard

treatment of syllogism in [9]).

A special case, as in the mental models theory of [9], is represented by the quantifier *no*: its meaning is represented by selecting all the tokens F representing the denotation of the noun it quantifies ($Q(F)=F$); but when the relation *rel* involving the NP is introduced, it is interpreted as negated either in the sense of a NCW(*rel*) relation or in the sense of being annotated as negated. As an example, in *no farmer owns a donkey* the owning relation, is transformed in a NCW(*own*) relation which keeps apart all the farmers from the set of donkeys.

(c) If the NP is an indefinite such as *a car*, two cases are possible according to the presence of a negation and the role played by the NP in the main predicate:¹

- If the NP is the subject of the verb or it appears in a non-negated relation, a single new token representing a car is added to the matrix T of the model and annotated as "...", since it does not convey any uniqueness presupposition.
- If the NP appears in a negated predicate and it is not the subject of the predicate *rel*, some tokens representing the denotation of the noun $F = \{x_1, \dots, x_n\}$ are introduced in T and appear in a NCW(*rel*) relation to keep them separate from the other tokens of the model.²

(d) If the entity in the network W is the interpretation of a definite NP or a definite pronoun, then an antecedent must be searched for in the mental model constructed so far; according to the number, one or more tokens existing in the model are sought in T to act as the potential referents: further, the set of relations R must satisfy the description provided by the NP. This kind of unification, however, cannot be accomplished with items which are linked to other ones only by a NCW(*rel*) relation in which they appear in a non-subject role $\{t_i | \exists \text{rel}, x_1, \dots, x_n (\langle \text{NCW}(\text{rel}), x_1, \dots, t_i, \dots, x_n, \emptyset \rangle \in R \wedge i \neq 1)\}$, i.e., these items are implicitly assumed as 'non existing' in the model. Moreover, if the set of possible referents $X = \{t_1, \dots, t_n\}$ is composed of a subset of tokens which occur in relations with other tokens and a subset of tokens which are unrelated:

$\{t_i | \exists \text{rel}, A, x_1, \dots, x_n (\langle \text{rel}, x_1, \dots, t_i, \dots, x_n, A \rangle \in R)\} \cup \{t_j | \neg \exists \text{rel}, A, x_1, \dots, x_n (\langle \text{rel}, x_1, \dots, t_j, \dots, x_n, A \rangle \in R)\}$

then only the former set can be considered by the uni-

¹Note that *John does not love a girl in his office* where the indefinite is a *specific* one (see [10]) and the speaker could identify a unique referent for it, is not covered by this rule.

²This treatment of indefinites is justified also from a linguistic point of view. As [10] notice, the negation of a verb must be interpreted as having an inner scope which does not include the subject of the verb, otherwise sentences as *someone does not like a Porsche* would be true in case there is no people at all. And it finds a similarity in DRT where indefinites inside the scope of a negation are interpreted in a subordinate DRT structure which will not be accessible for the resolution of anaphoric expressions.

fication process (e.g., in the interpretation of *John has many donkeys. They are pink* where the model includes a number of donkeys but only a subset of them is related with John: the pronoun *they* refers only to this subset).

Note that the set of annotations is not constrained to be empty: in fact, it is possible to make reference to a set of entities which is involved in a negated relation as in: (6) *the soldier didn't see some of the enemies. They were hiding in the trees.*

Finally, since a definite pronoun is a *definite* reference, the found referent must be non-ambiguous: if different possibilities exist, then, for pragmatics reasons, the reference fails (see example (3)).

2. If the entity node of the NP np_1 is "dependent on" another node which is built from the NP np_2 , its interpretation depends on the one of np_2 : this means that, for each token built in correspondence with np_2 the interpretation of np_1 must be repeated according to the rules in 1 described above for non-dependent NPs. In particular, if np_1 is a singular *indefinite* and the corresponding relation is not negated, a new token is introduced for each token associated with np_2 ; if np_1 is plural, a different set of example tokens is added to the model for each token associated with np_2 .

For example in the distributive interpretation of *Every farmer has a donkey. They beat it, they* is unified with the tokens f_1, \dots, f_n representing farmers, but the interpretation of *it* (which in this reading cannot but be dependent on *them*) is performed for each f_i ($1 \leq i \leq n$) relatively to the set of tokens $\{t_j \mid \exists \text{rel}, x_1, \dots, x_n (<\text{rel}, x_1, \dots, f_i, \dots, t_j, \dots, x_n, \emptyset> \in R)\}$. In the example, for each i , *it* is unified with the d_i such that $<\text{beat}, f_i, d_i, \emptyset>$.

3. Finally, the tokens are linked by the relations described by the predicates. The number of relations which are introduced depends on the *set* or *individual* interpretation of the DAS of the NPs involved: if an NP is considered as a set, the tokens resulting from its interpretation are included as a whole in the role they play in the relation. Otherwise, each element of the set is introduced in different instance of the relation.
4. As we discuss in the following Section, the interpretation of a sentence which includes logical connectives can result in more than one model. The rule 1 is iterated for each of the clauses in the complex sentence. During the interpretation process some of the possible models must be discharged as inconsistent. This is a correct move but it can lead to the refutation of the sentence for pragmatic reasons (as in example (11) below). In fact, if the interpretation of a sentence results in a reduced set of models which can be better described by another sentence (that is, its interpretation does not discard any model), then by the Gricean principle of cooperation, the speaker should have used it instead of the one he chose.
5. On the other hand, if the interpretation of the sentence leads felicitously to a set of models, these models be-

come part of the context. When a subsequent sentence is interpreted, its interpretation must be compatible with *all* the models in the context. In particular, if the interpretation of the subsequent sentence produces more than one model, for each model in the context, at least one of the newly constructed models must be compatible (even if not the same one for all the model in the context). Otherwise, the sentence will be rejected (as in example (14) below).

Logical connectives

According to [10] the interplay of anaphora and logical connectives is a fundamental testbed for any theory of language interpretation. Here, the meaning of connectives is expressed by their possible models in [9]'s style. First the implicit models are constructed and if necessary the explicit ones are fleshed out.

Let's start with a simple example involving negation: (7) **John does not own a car. He washes it.*

Since, according to the representation outlined in the previous section, cars are included in NCW(own) relations, no referent can be found in the model for the pronoun *it*: $<T = \{\{\emptyset, c_1\}, \{\text{john}, \emptyset\}\}, R = \{<\text{NCW}(\text{own}), \text{john}, c_1, \emptyset>, A = \emptyset\}>$

So, the sentence is not interpretable according to that reading.

An example a bit more complex is: (8) *No farmer has a car. *It is red.*

A sentence like *no farmer is rich* is represented by a NCW relation between farmers and rich people see rule 1.b. In our model, this relation is extended to arbitrary predicates. Hence, the first sentence produces a model where cars appear in the set of *never connected with* entities, so that the interpretation (and failure in integration) is exactly the same as in the previous example:

$<T = \{\{\{\emptyset, c_1\}\{\emptyset, c_2\}\{\emptyset, c_3\}\}, \{\{f_1, \emptyset\}, \{f_2, \emptyset\}, \{f_3, \emptyset\}\}\}, R = \{<\text{NCW}(\text{own}), f_1, c_1>, \emptyset>, <\text{NCW}(\text{own}), f_2, c_2>, \emptyset>, <\text{NCW}(\text{own}), f_3, c_3>, \emptyset>\}, A = \{\dots\}>$

On the contrary: (9) *No farmer has a car. They prefer donkeys.* is acceptable, in spite of the negation appearing in the subject NP and of its singular number. In fact, the farmers (appearing as 'existing' entities) are available for integration.

If we now consider conjunctions and disjunctions, another interesting anomaly arises:

(10) *John owns a car; and Fred washes it;*

(11) **John owns a car; or Fred washes it;*

The syntactic structures are identical but the acceptability is not. In order to explain this fact, [10] introduced an accessibility constraint at the structural level: "*no disjunct of a disjunctive condition is accessible from any other*".

The mental model representation of a conjunction involves the inclusion in the same model of the conjoined sentences. So, no problem arises with (10), since the referent for *it* can be found in the same model where the second conjunct must be integrated. Compare the unacceptability of **John does not have a Porsche and Fred washes it.*

On the contrary, a disjunction $A \vee B$ requires the construction of two *separate* models (one with A and one with B). So, in the second model of (11) there is no available referent for the pronoun (B, i.e., *Fred washes it*). But when a difficulty (such as the impossibility of understanding a sentence) occurs in a mental model, the model can be manipulated and fleshed out; in principle, when applied to the second model (B), this process could produce two alternatives. In the first one John owns a car (A and B), while in the second one he does not (not A and B, i.e., *John does not have a car and Fred washes it*). So, it seems that the first extension could solve the problem: John, in fact, owns a car and Fred washes it:

The lower part of the figure shows the three resulting models: the second one (A and B) includes the first (A) and the third (not A and B) is discharged since Fred cannot wash a car which does not exist (see the * in the third box).

However, it seems that from any disjunction at least two distinct models must be constructed, and that none of them must be included in the other: otherwise, the common part of the two models would be necessarily true and according to Grice, the speaker should not have used a disjunction to express such a meaning (see rule 4 of the interpretation algorithm).

An example that supports the previous analysis is the acceptability of the following sentence, as the reader can easily test: (12) *John does not own a car or he washes it*. The second model (the one of *he washes it*) can be fleshed out with the negation of the first disjunct (not A and B, i.e., John does own a car and Fred washes it): after this extension, the resulting model puts at disposal the required referent for the pronoun. We are left with two different models, equivalent to the [10]'s interpretation of the example, i.e. *John does not own a car or John owns a car and he washes it*. In [10] this result is obtained by copying the negation of the first conjunct in the second DRS: such a rule, however, presupposes that disjunctions in natural language are always interpreted as exclusive disjunctions.

It is interesting to note that Dynamic Semantics [4], in order to explain this kind of examples, has to introduce a new class of anaphora, *E-type*.

The last connective to be considered is implication: (13) *If John owns a car, he washes it*.

This sentence involves two models (A and B, and not A to be further extended): in the first one, John owns a car and washes it, while in the second one he does not own any car. But, if the sentence is followed by (14) **It is a Porsche*, the pronoun of the second sentence can find a referent only in the first model in the context, while no antecedent is accessible in the second one (where the

car, in fact, is connected with a NCW relation). As prescribed by rule 4 of the algorithm, a new sentence must be integrated with all the pre-existing models in the context, otherwise it is unacceptable.

An analogous reasoning explains the oddity of **If John does not own a car, Fred washes it*. Moreover, so called *examination sentences* as (15) *no students will be admitted to the exam unless they have registered four weeks in advance* can be dealt with by interpreting the conjunction *unless* as an *if not* or a stronger *exclusive or*.

Plurals

A number of interesting anaphoric phenomena are related to *plurals*. The first situation concerns a plural pronoun referring to a set of singular antecedents which occur in the model: (16) *Mary met John. They talked*.

Even if in mental models the first sentence introduces separately two tokens, the rule 1.d can cope with these cases as if they were introduced simultaneously as by the NP *two people*. So it can resolve the anaphora without explicitly *summing* the antecedents to form a plural discourse referent, as DRT does.

Quantifier phrases such as *many of the farmers* do not always introduce the referents with which subsequent pronouns will be co-referential. For example, those pronouns refer to sets that have to be constructed from explicit information in the text. Here, quantifiers introduce in the model a set of tokens which pronouns can refer to in the subsequent discourse: (17) *Susan has found every book which Bill needs. They are on his desk*.

To resolve *they* we need only the set of tokens introduced in the model by the analysis of the first sentence. The right subset of books is identified in the model thanks to rule 1.d (see discussion below). In DRT, in contrast, a new discourse referent is constructed via an *abstraction* rule which copies the content of the DRSs introduced by the previous sentence.

In some approaches, definite NPs and pronouns inside the scope of a quantifier are considered like bound variables in a logical system. In (18) *every waiter wants customers to give him large tips* the pronoun does not seem to refer to any particular entity, while it does in (19) *John wants customers to give him large tips*. DRT in order to deal with both cases in a uniform way introduces the notion of discourse referent which does not correspond directly to any individual in the world, while providing antecedents for the pronouns.

In contrast, mental models theory allows unifying both cases, since quantifier phrases, in an extensional representation introduce sets of entities in the model.

Not all definite pronouns following quantifiers behave like bound variables, in particular, if they appear in a following clause, i.e., outside the quantifier scope: (20) *few congressmen admire Kennedy and they are very junior*. *They* refers to those (few) congressmen who admire Kennedy, even if there is no such an expression referring to them. If the pronoun were interpreted as a variable, the sentence would be equivalent to (21) *Few congressmen admire Kennedy and are very junior*. In [5]'s terms, there

is an *antecedent trigger*, a linguistic expression which introduces the antecedent of the pronoun but it does not have the same referent of the pronoun.

In our model, after the interpretation of the first clause the mental model contains the set of congressmen and a (small) subset of them which are in an "admire" relation with Kennedy. For rule 1.d above, the definite pronoun *they* can be resolved with this subset.

But as it might be expected, quantifiers focus on the subset of the set specified by the head noun. Hence, the unification process must be suitably constrained. In: (22) *Some farmers of this valley own a donkey. They don't like cars*, the pronoun *they* can in principle refer either to the *farmers of this valley* who own a donkey or to the complement set; according to rule 1.d in the interpretation algorithm, if the set of candidate referents can be partitioned in different sets, the pronoun is unified only with the entities which are involved in a relation (of owning a donkey).

The possibility of a plural anaphor resolved against referents described by a singular indefinite is explained by rule 1.d which deals with the interpretation of dependent NPs in distributive readings (see the Figure on first page). In (23) *Every farmer owns a donkey. They are pink* the distributive reading expresses explicitly the plurality of donkeys so that the correct referents are available for the plural pronoun. In contrast, in (24) *Every farmer owns a donkey. *He is a wise man*, the singular definite pronoun *he* cannot be resolved, since we do not have any information to choose one of the farmers (see rule 1.d).

An example slightly more complex is: (25) *Three farmers own a donkey. They beat them*. The latter sentence can be interpreted only as far the second clause is interpreted with two individual readings of the NP without DEP-ON arcs between them (case 3 of Figure 1). In this case the donkeys who form the antecedent of *them* are related each by a different relation with the farmers. Which farmer is selected for relating with the beating relation to a given donkey? as in case of rule 2 the interpretation of an anaphor is performed exactly with respect to the other tokens which are linked to it by some relation. Indeed, in the context is maintained the relation between each farmer and the donkey he owns: hence, the interpretation of the sentence leads to a situation where each farmer beats the donkey he owns, and not a different one (as it happens in some formal models of anaphora).

Finally, plural and singular pronouns can be mixed: (26) *Every farmer owns a donkey. They beat it*. Since *it* in the second sentence is dependent on the subject *they*, the interpretation of the second sentence is parallel to the interpretation of the first: the object (*it*) can be resolved against an antecedent only if it is interpreted as dependent on the subject; according to rule 1.d of the interpretation algorithm, *they* is unified with the set of farmers appearing in the model and, again, since there is an explicit relation (*own*) linking each of them to a donkey, this link is followed to determine the (singular) referent of *it*.

Similarly, the so called *donkey sentence*, (27) *Every farmer who owns a donkey beats it*, is acceptable: the procedure first interprets the subject phrase, thus obtaining, in the wide-scope reading of the universal, a representation where each farmer has at least a donkey; then it extends the representation by searching for a referent through each relation $\langle \text{own}, f_i, d_i, \emptyset \rangle$; so, in the distributive reading the sentence, as in the example above, for each farmer, a different referent for *it* is found, i.e. the donkey owned by him. The possible antecedent must satisfy the restriction carried by the number of the singular pronoun (compare **Every farmer who has two donkeys beats it*).

Conclusion

Since mental models are a cognitively plausible theory of human reasoning, they can be also useful in finding an explanation of linguistic phenomena. In [3], we exploited mental models to provide an explanation of lexically triggered presuppositions. In [2] more complex anaphorical phenomena related to the different readings of *donkey sentences* have been coped with in the same framework.

The limit of logical approaches in explaining anaphora is that they exploit representations that are not isomorphic to our conception of the described situation. The necessity of resorting to a referential level in explaining anaphora has been highlighted also by [7]. We followed his suggestion, but going in a different direction, where mental models replace the classical model-theoretic framework to provide a cognitively plausible approach to language interpretation.

Comparison and the development of knowledge

Lera Boroditsky (lera@mit.edu)

Cambridge, MA 02139 USA

Abstract

This paper considers the role of comparison in the development of knowledge. Results show that comparing similar objects makes them appear more similar, while comparing dissimilar objects makes them appear less similar. The effect of comparison on similar items was especially striking since subjects judged items to be more similar after comparison even if the comparison task was to list differences between the two items. Further, this effect appears specific to comparison and does not appear to be simply due to a "fleshing out" of object representations (listing properties of two objects without comparing the objects themselves served to increase the objects' similarity regardless of whether the objects were similar or dissimilar to start). This suggests that comparison may play a special role in partitioning bits of experience into categories, sharpening categorical boundaries, and otherwise helping us create conceptual structure above and beyond that offered by the world.

Introduction

Are our mental representations of things in the world simply a reflection of the structure of the world, or do we create new structures and partitions in conceptual space? Further, are our representations static, or do they change over time in systematic ways as a result of the way we process and use our knowledge? This paper suggests that some common cognitive processes (in this case, comparison) can introduce systematic biases into our representations of the world. These biases may be beneficial for separating out bits of experience into categories, sharpening categorical boundaries, and otherwise helping us create conceptual structure above and beyond that offered by the world.

This paper focuses on object similarity. Similarity is a central construct in explanations of cognition. Explanations of categorization, induction, learning, and memory all rely on the construct of similarity. Things that are similar are likely to end up in the same categories, are likely to support inductive inferences for each other, will aid in the learning of other similar things, and serve as good reminders for one another in memory. But where do similarities come from? Are similarities between objects apprehended immediately and automatically, or do they develop as a function of directed processing and experience?

This question has been taken up seriously in the study of categorization in the following form: Why do categories appear to contain similar things? Is it because similar things tend to end up in the same categories, or is it that putting two things in the same category makes them appear more similar? Previous research suggests that both are true. For

example, Goldstone, Lippa, and Schiffrin, (2001) showed that object representations can change as a result of category-learning, with objects assigned to the same categories becoming more similar (see also Kurtz, 1998). Further, previous research by Gentner and Namy (2000) suggests that providing children with an opportunity for comparison may help them in category learning by allowing them to discover deeper relational similarities between category members (see also Kurtz & Gentner, 1998).

This paper considers the role of comparison in the development of similarity. Results of four experiments suggest that comparison can play an important role in knowledge development. By making similar things appear more similar, and dissimilar things appear less similar comparison may help us partition bits of experience into categories and sharpen categorical boundaries.

Four experiments explore the effects of comparison on object representation. Experiments 1 and 2 examine the effects of comparison on the perceived similarity of similar and dissimilar objects. Experiment 3 contrasts the effects of comparison with those of simple "fleshing out" or elaboration of object representations. Experiment 4 extends the findings of Experiments 1 and 2 to novel objects.

Experiment 1

Method

Participants 132 Stanford University undergraduates participated in the study in order to fulfill a course requirement.

Materials Materials consisted of a one-page questionnaire. The top of the page contained line-drawings of 4 named familiar animals (a deer, a horse, a goat, and a donkey) as shown in Figure 1a. The rest of the page contained three questions. For 73 participants, the first question asked them to describe three similarities between two of the animals (e.g., "Please describe 3 similarities between the goat and the donkey.") For the other 59 participants, the first question asked them to describe three differences between two of the animals (e.g., "Please describe 3 differences between the goat and the donkey.") Participants were given three blank lines for their responses. Which two animals were chosen for comparison was counterbalanced across subjects such that each pair of adjacent shapes was the focus of comparison equally often. Which animal was named first in the comparison was also counterbalanced across subjects.

The last two questions asked participants to rate the similarity of the two animals they had just compared (e.g., "How similar are the goat and the donkey?"), and of the other two animals (e.g., "How similar are the deer and the horse?"). Half of the subjects rated similarity for the previously compared pair first, and the other half rated similarity for the other pair first. As before, which animal was named first in each comparison was counterbalanced across subjects. Subjects rated similarity on a 10-point scale (1=not similar and 10=very similar).

Procedures The one page questionnaire was embedded in a larger questionnaire packet which contained many other pages unrelated to this study. Participants completed the questionnaire at home on their own time.

Results

Comparing two similar items made people think of them as more similar. This was true regardless of whether the comparison involved naming similarities between the two items ($M=6.42$ after naming similarities, $M=5.93$ without naming similarities, $t=2.01$, $p<.05$) or naming their differences ($M=6.69$ after naming differences, $M=6.30$ without naming differences, $t=1.89$, $p<.05$). There was an overall effect of comparison ($F(1,130)=7.11$, $p<.01$) and no interaction between the two comparison types ($F(1,130)=.08$, $p=.78$).

Discussion

Experiment 1 showed that comparing two things (even when looking for their differences) can cause people to discover similarities between the two things. But why should the similarity of two objects increase after they are compared, especially if one's task is to describe their differences? One possibility is that in the process of finding and articulating differences, people are also finding similarities. As shown by Gentner & Markman (1994), the most meaningful (and easiest to name) differences are those that are attached to the structural similarities. On this view, because the process of comparison involves an alignment between two representational structures (see Markman & Gentner, 1993a, 1993b, 1996), discovering meaningful differences involves first establishing the similarities. To take a particular example, if one wanted to mention that the goat has a shorter tail than the donkey (a difference), this makes salient the fact that both animals have tails (a similarity).

But there could also be a less interesting explanation for these results. What if similarity only increases after comparison because people create a new feature for the things they compare, something like "thing I compared before." If this is the case, similarity might be increasing simply because the two things previously compared now both have this extra feature in common. One way to test this possibility, is to ask people to carry out comparisons between things that are so different, that no meaningful similarities are likely to be found. If comparison no longer

serves to increase perceived similarity, then it is the ability to find meaningful similarities (and not just the creation of an extra feature) that is responsible for the findings of Experiment 1. In Experiment 2, the pictures of four similar animals used in Experiment 1 were replaced with pictures of four quite dissimilar objects: a phone, a pretzel, a hat, and a football.

Figure 1: Stimuli used in Experiments 1 and 2 (shown in parts A and B respectively). Images were taken from Snodgrass, J. G., & Vanderwart, M. (1980).

Experiment 2

Method

Participants 61 Stanford University undergraduates participated in the study in order to fulfill a course requirement.

Materials Just as in Experiment 1, materials consisted of a one-page questionnaire. The top of the page contained pictures of 4 dissimilar objects as shown in Figure 1b. The rest of the page was constructed just as described for

Experiment 1. The comparison task for all 61 of the subjects was to name differences between two items.

Procedures The procedures were the same as in Experiment 1.

Results

First, the stimuli in this experiment were indeed perceived to be much less similar to each other ($M=2.60$) than those used in Experiment 1 ($M=6.50$), $F(1,118)=278.9$, $p<.001$. This was necessary as a manipulation check.

It turned out that comparing two dissimilar objects did not increase their similarity. In fact, naming differences between two dissimilar objects actually made participants think of the objects as less similar ($M=2.41$), than if they hadn't compared them before ($M=2.79$), $t=-1.89$, $p<.05$. This pattern was significantly different from that observed in Experiment 1 as confirmed in an interaction in a 2×2 repeated measures ANOVA (2 (named differences or not) \times 2 (stimuli similar or dissimilar)), $F(1,118)=6.90$, $p=.01$.

Discussion

Comparison appears to have different effects on similar and dissimilar objects. Comparing things that are similar can lead one to discover new (or highlight old) similarities, thereby increasing the perceived similarity of the two objects. Comparing things that are dissimilar on the other hand, is less likely to lead one to discover similarities (since there are fewer similarities there to be discovered). Hence, comparing two dissimilar things may serve to make the items less similar.

The results of Experiment 2 suggest that the increase in similarity following comparison in Experiment 1 was not simply due to subjects creating an extra feature (something akin to "thing I compared before") for items they were asked to compare. A co-history of comparison does not automatically result in higher similarity. Rather, it seems that only when meaningful similarities are to be found as a result of comparison, does comparison increase similarity.

However, there is one concern. At this point, it is not clear whether the difference observed between Experiments 1 and 2 is specifically a difference brought out by the process of comparison, or a more general difference inherent in the items. It could be that performing comparisons between items is simply serving to flesh out their representations, and it could be the differences inherent in these fleshed-out representations that produce the effects, and not the way comparison (*per se*) interacts with the representations. To explore this possibility, instead of asking subjects to perform comparisons between items, Experiment 3 asked subjects to list properties of the items separately (without comparing the items). This property-listing task was designed to flesh-out the representations without invoking the extra step of comparison. One group of subjects performed this task with the similar items used in Experiment 1, and another group of subjects performed the task with the dissimilar items used in Experiment 2.

Experiment 3

Method

Participants 234 Stanford University undergraduates participated in the study in order to fulfill a course requirement. Of these, 119 completed the task with similar items from Experiment 1 and 115 completed the task with dissimilar items from Experiment 2.

Materials Just as in Experiments 1 and 2, materials consisted of a one-page questionnaire. The top of the page contained either pictures of the 4 similar animals shown in Figure 1a or the 4 dissimilar objects shown in Figure 1b. Instead of being asked to name differences between two of the items, participants were asked to name properties of two of the items separately (e.g., "Please describe 3 properties of the phone." followed by 3 blank lines for participants to fill in and further followed by "Please describe 3 properties of the pretzel." again followed by 3 blank lines.) All of the counterbalancing and the rest of the page was done just as described for Experiment 1.

Procedures The procedures were the same as Experiment 1.

Results

Participants judged items to be more similar if they had previously been asked to name their properties than if they hadn't. This was true for both the similar items from Experiment 1 ($M=6.34$ after naming properties, and $M=5.92$ without naming properties, $t=1.90$, $p<.05$) and the dissimilar items from Experiment 2 ($M=3.37$ after naming properties, and $M=2.97$ without naming properties, $t=2.14$, $p<.02$). This pattern for the dissimilar items was significantly different from that observed in Experiment 2 as confirmed in an interaction in a 2×2 repeated measures ANOVA (2 (items were focused or not) \times 2 (comparison or property-listing)), $F(1,174)=6.817$, $p=.01$.

Discussion

Unlike comparison, listing properties of individual items did not have a different effect on similar and dissimilar items. Whereas comparison served to increase the similarity only for similar items, property-listing increased similarity for both similar and dissimilar items. The process of comparison appears to have the special effect of selectively increasing the similarity of similar items (and possibly decreasing the similarity of dissimilar items). Simply fleshing out the representations (by listing properties) was not sufficient to have this effect.

It appears that the process of comparison could play a crucial role in the development of knowledge. However, the studies so far have only tested the effects of comparison on familiar items, things that people already have representations for. Can comparison play a similar role

even when people are just learning about something new? To investigate this, novel shapes were used in Experiment 4.

Figure 2: Stimuli used in Experiment 4. More similar items are shown in part A and less similar items are shown in part B. Images provided by Michael J. Tarr (Brown University) and Pepper Williams (University of Massachusetts).

Experiment 4

Method

Participants 188 Stanford University undergraduates participated in the study in order to fulfill a course requirement.

Materials Just as in Experiment 1, materials consisted of a one-page questionnaire. The top of the page contained color pictures of 4 named novel shapes. One set of questionnaires used the 4 similar objects shown in Figure 2a, and the other used the dissimilar objects shown in Figure 2b. The rest of the page was constructed just as in Experiment 1, with the following two differences: (1) all of the participants were asked to focus on differences (none named similarities)

between the shapes, and (2) before being asked to verbally describe the differences, participants were asked to circle three differences between two of the novel shapes on the pictures themselves (e.g., "Please circle 3 differences between Chico and Harpo.") The rest of the page was constructed and counterbalanced just as for Experiment 1.

Procedures The procedures were the same as Experiment 1.

Results and Discussion

First, a manipulation check: participants indeed judged the "similar" items in Figure 2a to be more similar ($M=3.84$) than the "dissimilar" items in Figure 2b ($M=2.37$), $F(1,186)=36.6$, $p<.001$.

The effects of comparison were exactly as predicted by Experiments 1 and 2. Naming differences between two similar shapes (Figure 2a), again made people think of the two shapes as more similar ($M=4.09$ after naming differences, and $M=3.58$ without naming differences, $t=2.83$, $p<.01$). Naming differences between two dissimilar shapes (Figure 2b), on the other hand made people think of the two shapes as somewhat less similar ($M=2.31$ after naming differences, and $M=2.43$ without naming differences, $t=-.61$, $p=.27$). The patterns for similar and dissimilar items were significantly different from each other as confirmed in an interaction in a 2x2 repeated measures ANOVA (2 (named differences or not) X 2 (stimuli similar or dissimilar)), $F(1,186)=4.43$, $p<.05$.

It appears that the process of comparison had the same effect on novel items as it did on familiar items in Experiments 1 and 2. Comparing two similar novel items made them appear more similar, while comparing dissimilar novel items made them appear less similar.

General Discussion

The studies described in this paper examined the effects of comparison on perceptions of similarity. It appears that comparison can alter people's representations of objects by leading them to discover (or take note of) new similarities and differences. In future studies, it would be interesting to see how long effects of comparison last, and if these effects also extend to categorization. Previous research by Gentner and Namy (2000) suggests that this may indeed be the case. Further studies looking directly at the effects of comparison on categorization would be an interesting extension of this research.

Also worthy of further investigation are the interactions between similarity, structural alignability, and the process of comparison. In the studies reported in this paper, comparison was found to have different effects on similar versus dissimilar items (making similar items more similar, and dissimilar items less similar). However, the similar items used in these experiments were similar in several different ways: for example, both in terms of surface features and in deeper structural ways. Since several kinds of similarity were confounded, it is not clear which of these aspects contributed to the effect. In future studies it would

be interesting to investigate the separate contributions of structural and surface similarity as they interact with the comparison process. These further studies should also shed more light on why comparison has the effect it does.

Conclusions

Four studies showed that comparing similar objects makes them appear more similar, while comparing dissimilar objects makes them appear less similar. This was true for both novel and familiar objects. The effect of comparison on similar items was especially striking since subjects judged items to be more similar after comparison even if the comparison task was to list differences between the two items. Further, this effect appears specific to comparison and does not appear to be simply due to a "fleshing out" of object representations. When subjects were only asked to list properties of objects without comparing the objects themselves, the perceived similarity of the objects increased regardless of whether the items were similar or dissimilar to start. By making similar things appear more similar, and dissimilar things appear less similar, comparison may play a special role in category development. Further, it appears that even incidental conceptual experience (e.g., happening onto one comparison versus another) can play an important role in knowledge development.

These results suggest that common cognitive processes like comparison can introduce systematic biases into our representations of objects and their similarities. These biases may be beneficial for separating out bits of experience into categories, sharpening categorical boundaries, and otherwise helping us create conceptual structure above and beyond that offered by the world.

Abstract

Does the language you speak shape the way you think about the world? Four studies investigate how English and Indonesian speakers encode and represent action events. Unlike English, Indonesian verbs do not include tense markers. Indonesian speakers are not required to indicate whether an event has already occurred, is happening now, or will occur in the future. Does needing to include tense to speak English grammatically change the way English speakers pay attention to, encode and remember events? We find cross-linguistic differences in memory and similarity judgments between English and Indonesian speakers, as well as between Indonesian-English bilinguals tested in English and Indonesian.

Introduction

Humans communicate with one another using a dazzling array of languages, and each language differs from the next in innumerable ways (from obvious differences in pronunciation and vocabulary to more subtle differences in grammar). For example, to say that “the elephant ate the peanuts” in English, we must include tense - the fact that the event happened in the past. In Mandarin and Indonesian, indicating when the event occurred would be optional and couldn’t be included in the verb. In Russian, the verb would need to include tense and also whether the peanut-eater was male or female (though only in the past tense), and whether said peanut-eater ate all of the peanuts or just a portion of them. In Turkish, one would specify (as a suffix on the verb) whether the eating of the peanuts was witnessed or if it was hearsay. Speakers of different languages have to attend to and encode strikingly different aspects of the world in order to use their language properly (Sapir, 1921; Slobin, 1996). Do these quirks of languages affect the way their speakers think about the world? Do English, Mandarin, Russian, and Turkish speakers end up attending to, partitioning, and remembering their experiences differently simply because they speak different languages?

The relationship between language and thought is one of the most central questions in Cognitive Science. The universality of mental representations (whether or not

speakers of different languages think differently about the world) has long been at the center of a controversy attracting thinkers from Plato to Chomsky, but despite much attention and debate, definitive answers have not been forthcoming. The idea that thought is shaped by language is most commonly associated with the writings of Benjamin Lee Whorf (Whorf, 1956). Whorf, impressed by linguistic diversity, proposed that the categories and distinctions of each language enshrine a way of perceiving, analyzing, and acting in the world. In so far as languages differ, their speakers too should differ in how they perceive and act in otherwise objectively similar situations. This strong Whorfian view—that thought and action are entirely determined by language—has long been abandoned in the field. However, definitively answering less deterministic versions of the “does language shape thought” question has proven a very difficult task. Some studies have claimed evidence to the affirmative (e.g., Boroditsky, 2001; Bowerman, 1996; Davidoff, Davies, & Roberson, 1999; Gentner & Imai, 1997; Levinson, 1996; Lucy, 1992; Dehaene, Spelke, Pinel, Stanescu, & Tsivkin, 1999; Hermer-Vasquez, Spelke, & Katsnelson, 1999; Spelke & Tsivkin, 2001), while others report evidence to the contrary (e.g., Heider, 1972; Malt, Sloman, Gennari, Shi, & Wang, 1999; Li & Gleitman, in press).

One possible resolution to this debate might be that some conceptual domains are more susceptible to linguistic influence than others. For example, Gentner and Boroditsky (2001) have argued that the effect of language should be most apparent in the conceptualization of relations (typically encoded by verbs and spatial prepositions). In general, the lexicalization of actions and relations varies much more cross-linguistically than does the lexicalization of object categories, and picking out the extent and generality of a relational concept requires considerable experience with language. Recent research has supported this view (Gillette, Gleitman, Gleitman, & Lederer, 1999). For example, in one study, adults watched silent films of mothers talking to their children and tried to guess what was being said. Given only the silent film, adult participants were able to correctly guess nouns three times more often

than verbs (45% and 15% correct respectively). Further, concrete activity verbs like 'push' were much more easily guessed from silent observation than from the syntactic frames in which they were used (50% and 15% respectively), whereas verbs that denote more abstract activities like 'think' were much more easily guessed from syntax than from observation (90% and 0% respectively). It appears that acquiring representations of actions, relations, and events requires experience with language. This suggests that the eventual form of these concepts may be importantly shaped by the language experience.

This paper examines a cross-linguistic difference in verb syntax between Indonesian and English, and its effects on people's representations of action events.

Unlike English, Indonesian verbs do not include tense (they do not indicate whether the event or action took place in the past, is taking place in the present or will take place in the future). While Indonesian speakers may use other temporal words (e.g., just now, or soon) to communicate this information, these temporal markers are optional, and the tense of an action is often left to be inferred from context.

For example, in order to describe the three pictures shown in Figure 1, an English speaker might say (from left to right) "John is about to kick the ball," "John is kicking the ball," and "John has kicked the ball." In Indonesian all three pictures would likely be described by the same sentence, roughly "John kick ball." Does this difference between how English and Indonesian speakers talk about action events lead to differences in how the two groups attend to, encode, and represent the events?

We report four studies aimed at uncovering differences and similarities between Indonesian and English speakers in terms of how they encode and represent actions and events.

Figure 1: Example of action in three different tenses.

Experiment 1

Experiment 1 examined whether speaking a tensed language makes English speakers think of actions in different tenses as less similar, and actions in the same tense as more similar. English and monolingual Indonesian speakers were shown pairs of pictures that show either two different actors performing the same action in the same tense, or the same actor performing the same action in two different tenses (as shown in Figure 2). Subjects were asked to rate the similarity of a large set of such pairs (on a 9 point scale where 1=not similar and 9=very similar). The linguistic difference between the two languages predicts that English

speakers will rate same-tense pairs more similar than will Indonesian speakers, but will rate different-tense pairs less similar than will Indonesian speakers.

Methods

Participants 14 native English and 12 monolingual Indonesian speakers participated in this study in exchange for payment. The English speakers were recruited and tested at MIT, and the Indonesian speakers were tested in Jakarta. None of the Indonesian speakers had learned English.

Materials A set of 90 pictures served as stimuli for this experiment. The pictures portrayed 10 different actions, each action performed by three different actors. For each actor performing a particular action there were 3 versions showing the actor about to perform the action, doing the action, and having done the action (as shown in Figure 1). The actions were: kicking a ball, throwing a frisbee, eating a banana, drinking orange juice, ripping a sheet of paper, cutting a rope, hula-hooping, lifting a very large ball, pouring dark liquid out of a clear container, and opening an umbrella. The actions were chosen to be sufficiently different from one another to ensure generality.

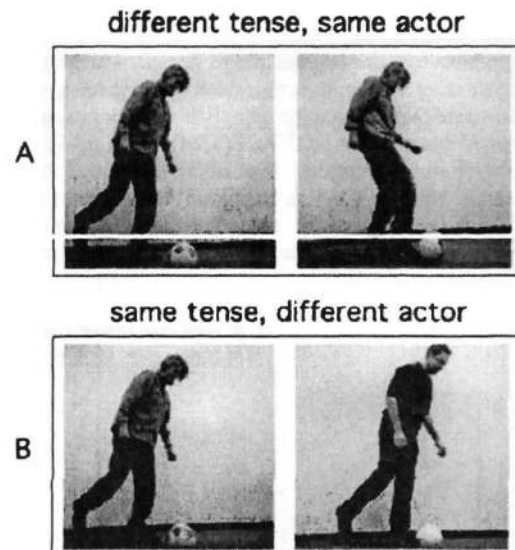

Figure 2: Examples of picture-pairs used.

Design A set of 180 picture pairs were created. Half of these showed the same actor performing the same action in different tenses (as shown in Figure 2A), and half showed two different actors performing the same action in the same tense (as shown in Figure 2B). All possible combinations of pictures that yielded such pairs were used (a total of 180 pairs).

Procedure Participants were tested individually in a quiet room. English speakers were given instructions in English, and Indonesian speakers were given instructions in Indonesian. The English instructions were: "You will see two pictures each time. Your task is to rate how similar those two pictures are. In rating them, use the numbers 1 through 9: 1 for NOT similar at all, 9 for VERY similar." The Indonesian instructions were: "Setiap kali, Anda akan melihat dua gambar. Kami minta agar Anda mengatakan seberapa mirip dua gambar itu. Gunakan angka 1 sampai dengan 9. 1 untuk SANGAT TIDAK MIRIP, 9 untuk MIRIP SEKALI."

The participants were also told that all of the pairs would be pretty similar, but they should still try to use the whole range of similarity ratings from 1 to 9.

A computer presented the 180 pairs in a new random order for each subject. Each pair stayed on the computer screen until the subject pressed a key (1 through 9) to indicate their similarity rating.

Results

Results are shown in Figure 3. As predicted, English speakers rated same-tense pictures (involving different actors) more similar than did Indonesian speakers ($M=6.34$ for English speakers, and $M=4.82$ for Indonesian speakers), $t=2.07$, $df=24$, $p<.05$. Further, as predicted, English speakers rated different-tense pictures less similar than did Indonesian speakers ($M=5.56$ for English speakers, and $M=6.64$ for Indonesian speakers), $t=1.71$, $df=24$, $p<.05$. The difference between the two language groups was confirmed as an interaction between comparison type (between-tense or within-tense) and language (English or Indonesian) in a 2×2 repeated measures ANOVA, $F(1,24)=4.41$, $p<.05$. This pattern of findings suggests that using the English tense system may change English speakers' representations of actions, making differently tensed actions appear more distinct and actions in the same tense appear more similar.

Figure 3: Results of Experiment 1.

Discussion

English and Indonesian speakers appeared to focus on different aspects of action scenes in making their similarity comparisons. English speakers seemed to hone in on tense, judging actions in the same tense but performed by different actors (as shown in Figure 2b) to be more similar than actions performed in different tenses but by the same actor (as shown in Figure 2a). The Indonesian speakers showed the opposite pattern, appearing to ignore similarity of tense in favor of similarity of actor.

This raises two further questions: (1) Do Indonesian speakers who learn the English tense system change the way they think about events? and (2) Do Indonesian-English bilinguals think differently when speaking Indonesian than when speaking English? Experiment 2 tested Indonesian-English bilinguals both in Indonesian and in English on the same task as described in Experiment 1.

Experiment 2

Methods

All of the materials, design and procedure were exactly as described for Experiment 1. Seventeen Indonesian-English bilinguals participated in this study. Seven were tested in English and ten were tested in Indonesian. All of the participants were native speakers of Indonesian and were matched on their amount of experience with English.

Results and Discussion

Figure 4: Results of Experiment 2.

Results are shown in Figure 4. Indonesian-English bilinguals rated same-tense pictures (involving different actors) more similar when they were tested in English than when tested in Indonesian, ($M=6.64$ when tested in English, and $M=5.27$ when tested in Indonesian). Further, Indonesian-English bilinguals rated different-tense pictures less similar when they were tested in English than when

tested in Indonesian ($M=5.11$ when tested in English, and $M=5.42$ when tested in Indonesian). The difference between the two groups was confirmed as an interaction between comparison type (between-tense or within-tense) and language of testing (English or Indonesian) in a 2×2 repeated measures ANOVA, $F(1,15)=4.40$, $p<.05$.

This pattern of findings suggests two things. First, it appears that bilinguals do think differently when speaking different languages. Even though the task was conducted in pictures, setting a linguistic context by providing instructions either in English or in Indonesian changed the way Indonesian-English bilinguals reasoned about the action events in this study.

Second, it appears that learning a new language can change the way one thinks. The Indonesian-English bilinguals who were tested in Indonesian showed a pattern that was somewhere in-between the pattern shown by monolingual Indonesian speakers and the pattern shown by English speakers. Even though they were tested entirely in Indonesian it appears that having learned English may have changed the way they think about action events. Further studies will be necessary to explore this possibility in more detail.

Experiment 3

Although the findings of Experiments 1 & 2 are very suggestive, the similarity-ratings task used is subjective and may tell us more about the participants' cognitive preferences than about their cognitive performance. Could cross-linguistic differences lead to difference in cognitive performance and not just preference?

Experiment 3 was designed to test Indonesian and English speakers' ability to remember action events. Subjects were shown pictures of people performing actions (the same pictures were used as in Experiments 1 & 2). During the learning phase, each subject saw a person performing an action in one of three tenses (e.g., they may have seen only the middle panel of Figure 1). During the test phase, subjects were shown pictures of that person performing the action in all three tenses (as shown in Figure 1) and asked to choose which one they had seen previously. We predicted that English speakers should be better than Indonesian speakers at encoding and remembering the tense in which they witnessed an action.

Methods

Participants 13 native English and 18 monolingual Indonesian speakers participated in this study in exchange for payment. The English speakers were recruited and tested at MIT, and the Indonesian speakers were tested in Jakarta. None of the Indonesian speakers had learned English.

Materials and Design All of the same pictures as described for Experiment 1 were used. During the learning phase, subjects were shown 30 of the 90 pictures (1 picture of each

person doing each action in only one of the possible 3 tenses). At test, subjects were shown all three pictures of a person performing an action in all 3 tenses (all three pictures were presented simultaneously) and asked to choose which one they had seen earlier.

Procedure Participants were tested individually in a quiet room. English speakers were given instructions in English, and Indonesian speakers were given instructions in Indonesian. Participants were told to simply look at the pictures and try to remember everything they saw. Participants were not instructed to encode the pictures linguistically.

A computer presented the pictures in a new random order for each subject (both for the learning and test sets). During the learning, each picture was shown only once and stayed on the screen for 3 seconds. During the test, the pictures stayed on the screen until the subject made a response (by pressing 1, 2, or 3 on the keyboard to correspond to which picture they thought they had seen previously).

Results

Results are shown in Figure 5. As predicted, English speakers were better able to remember which of the three tense versions of a picture they had seen before. English speakers were able to pick the correct answer 41% of the time, as compared to Indonesian speakers who only succeeded 31% of the time, $t=1.72$, $df=29$, $p<.05$. Indonesian speakers were not better than chance at recognizing the picture they had seen before (chance=33.3%).

Figure 5: Results of Experiment 3.

Discussion

Results of Experiment 3 suggest that experience with particular languages may affect not only people's cognitive preferences, but also aspects of their performance on basic cognitive tasks (such as memory). However, it is possible that differences in memory performance between English and Indonesian speakers observed in this task are not due to linguistic differences, but rather to other differences in cultural upbringing or education. It is quite possible that the English speakers included in this sample (mostly MIT undergraduates) have received more training in memorization than the Indonesian speakers in our sample. In order to control for such differences, Experiment 4 tested Indonesian-English bilinguals (who were matched on educational and cultural background) either in English or in Indonesian in the same task as described for Experiment 3. By keeping constant educational and linguistic background and only varying the language of testing we can test whether speaking one language versus another can really affect aspects of one's cognitive performance.

Experiment 4

In Experiment 4, Indonesian-English bilinguals were tested either in Indonesian or in English in the same memory task as described for Experiment 3.

Methods

All of the materials, design and procedure were exactly as described for Experiment 3. Eighteen Indonesian-English bilinguals participated in this study. Seven were tested in English and eleven were tested in Indonesian. All of the participants were native speakers of Indonesian and were matched on their linguistic and educational background.

Results and Discussion

Results are shown in Figure 6. As predicted Indonesian-English bilinguals were better able to remember the tense of actions when they were tested in English (40% correct) than when they were tested in Indonesian (26% correct), $t=1.76$, $df=16$, $p<.05$. When they were tested in Indonesian, Indonesian-English bilinguals did not perform better than chance (in fact, slightly worse).

These results suggest that even something as subtle as linguistic context (whether instructions were given in English or Indonesian) can have an effect on how people encode and represent events. Even though subjects were not asked to encode the events linguistically (and the entire task was conducted in pictures), people's ability to remember the tense of events they had witnessed (whether they saw someone about to kick a ball or having already kicked a ball) depended on whether or not tense distinctions were required in the language in which they had been greeted and given instructions just prior to the task.

Figure 6: Results of Experiment 4.

Summary

Four studies investigated the effect of linguistic experience on how people attend to, encode, and represent action events. The results suggested that experience with the English tense system makes English speakers think of actions in the same tenses as more similar and action in different tenses as less similar. Unlike English speakers, Indonesian speakers did not appear to value tense in making their similarity judgments. Further, English speakers were better able to remember the tense of an action they had witnessed than were Indonesian speakers (who did not perform above chance on the memory task).

Studies that tested Indonesian-English bilinguals in either English or Indonesian provided further insights about how language may affect thinking. Both in memory and similarity ratings, the language that bilinguals were tested in had an effect on the subjects' performance in the task. Indonesian-English bilinguals looked just like English speakers when tested in English, and much more like Indonesian speakers when tested in Indonesian. Further, results of the similarity study suggested that learning a new language can change the way one thinks – Indonesian-English bilinguals tested in Indonesian showed a pattern of results that was somewhere in-between the English-speakers' pattern and that shown by monolingual Indonesian speakers.

Overall, it appears that representations of action events are not universal. Experience with the English tense system appears to segment actions into distinct temporal categories that are not basic or universal to human cognition. Further, even something as subtle as linguistic context (here, the language in which instructions are given for a non-linguistic task) appears to have a striking effect on how people encode and represent their experiences.

It appears that speakers of different languages do attend to, partition, and remember their experiences differently, simply due to the implementational differences of the languages they speak.

Atomistic and Systems Approaches to Consciousness

Andrew Brook (abrook@ccs.carleton.ca)

Luke Jerzykiewicz (ljerzyki@ccs.carleton.ca)

Cognitive Science, Carleton University, Ottawa, Ontario, Canada

Abstract

The approach to consciousness taken by most philosophers is very different from the approach taken by most cognitive psychologists, so different that one could be forgiven for wondering if they are talking about the same thing. Most philosophers focus on individual psychological states. By contrast, most psychologists focus on properties of cognitive systems as a whole such as global workspace or attention. (Some philosophers favour this approach, too, Dennett and P. M. Churchland for example.) We will expose some of the peculiarities of the dominant philosophical approach and, by looking briefly into what is needed to give an adequate account of consciousness, advance some reasons for favouring the approach dominant among psychologists.

Two Approaches to Consciousness

Reading recent writings on consciousness by philosophers and cognitive psychologists, one could be forgiven for wondering if they are talking about the same thing. Most philosophers focus on individual psychological states – individual perceptions or feelings or imaginings – or at most tiny combinations of such states (Rosenthal, 1991; Chalmers, 1996; Tye 1995). Experimental psychologists by contrast focus on properties of cognitive systems as a whole: global workspace (Baars 1988), intermediate level of processing (Jackendoff 1987), or attention. Attention has been particularly singled out for ... attention. For Posner or Mack and Rock, for example, to be conscious of something simply is to pay attention to it (Posner 1994; Mack and Rock 1998).

First we will lay out the main contours of the two dominant approaches, starting with the one favoured by most philosophers (though not all: both Dennett (1991) and P. M. Churchland (1995) favour the approach taken by psychologists). Then we will assess them. There are serious *prima facie* shortcomings in the dominant philosophical approach, but there is also a serious worry about the dominant psychological approach. To bring out these shortcomings and this worry, we will need to distinguish two kinds of consciousness and lay out some of the things that an adequate account of consciousness must explain.

The dominant approach in philosophy

Two things characterize the dominant approach to consciousness in recent philosophical work on the topic. The first is a kind of atomism. These philosophers tend to talk about conscious states one by one ('what is it like for something to look red?') or at most in tiny groups. In both cases, the cognitive system that has them is pretty much

ignored. (Theorists may add, '...look red to me' but they do nothing with the addition.) Almost the whole of the massive literature on *qualia* exhibits this feature. (*Qualia* are the felt quality of conscious states, 'what it is like to have them', in Thomas Nagel's (1974) famous phrase.) The thing that has such states, the subject of conscious states, is ignored. Let us call this view of consciousness *atomism*.

Atomism – the view that conscious states can be studied one by one or in small groups, without reference to the cognitive system that has them.

When you think about it, this atomism is remarkable. It seems obvious that consciousness does *not* come in atomically separable states in this way.

This atomism about consciousness goes with another view that we will call *local realism*. Local realism is the view that consciousness or what is distinctive about consciousness, for example that in virtue of which it is like something to have a psychological state, is a property of individual psychological states or tiny groups of psychological states.

Local realism – the view that consciousness or what is distinctive about consciousness is either a non-relational property of individual psychological states or a relationship among very small numbers of psychological states.

Specifically, this approach to consciousness views it as either a nonrelational property of single psychological states or, though a relational property, one that ties only very small groups of psychological states to one another. A relationship between one state and another single state would be an example. This account is not very precise but it is precise enough for our purposes. What matters is the contrast with the kind of properties that figure centrally in theories that view consciousness as a relationship between a great many psychological states and a conscious being

whose states they are.

Local realism is a realist view because it takes the states in question to be real, not postulated abstract entities that we believe in merely because of certain concepts or explanatory strategies or something of the kind.

There are (at least) three types of local realism. In one type, appearing red to me would be a property of an experience of red, being painful would be a property of a pain, and so on. We find a second type in what have come to be called transparency theories, theories holding that we see right through conscious states (hence transparency) and are conscious only of what such states are about. In this approach, something appearing red is not a property of any experience, it is a matter of experiencing something that appears to be red, feeling pain is a matter of experiencing something painful, and so on. In the third type, a representation of red gets to be conscious by being related to another psychological state, for example by being the object of a thought about that representation (Rosenthal's 1991 higher-order thought view of consciousness).

It might seem that atomism requires local realism but in fact that is not clear. Some atomists about consciousness are simply neutral about whether qualia, for example, are local or nonlocal properties of the states they discuss. This neutrality is a bit curious because these theorists believe that they can say other important things about qualia, e.g., that when it is like something to have a representation, this quale, this being like something, is radically different from other aspects of the representation, but neutral they have been. Nonetheless, local realism would certainly promote atomism: if consciousness is a local property of certain states, it would be at least very tempting to hold that one could study such states one by one and in isolation from the system that has them.

It is important to note that *local* realism about consciousness is not necessarily the same thing as *realism* about consciousness. Even if consciousness is not a local property of individual psychological states, it could still be a real property of cognitive systems as a whole. We mention this now because there have been influential treatments of consciousness recently that back off from any form of cognitive-system realism about consciousness, for example Davidson's (1996) view. In Davidson's view, consciousness arises out of a complex triangular interaction among oneself, other purposive beings, and the world. By itself, this triangulation picture need not depart from realism; the result of the triangulation, consciousness, could still be a real property of cognitive systems. For Davidson, however, not only does consciousness arise out of triangulation, it is (roughly) nothing more than triangulation. When triangulation results in stable attributions of consciousness to self and others, that is what consciousness is. And *this view is incompatible with most versions of realism about consciousness.*

One central issue in this atomist, local realist literature

is the relationship of consciousness to representation. At minimum, being conscious of something is *one way* of representing something. Of course, things can also be represented unconsciously. In fact, probably the vast bulk of our representations never make us conscious of anything. Certainly a representation does not need to make us conscious of anything to be cognitively active. But now ask: can the difference between conscious and nonconscious representation *be captured* by appealing to representational properties or are the properties that make a state conscious nonrepresentational properties? Here there is a major split in the atomist, local realist camp, with some researchers opting for the representational alternative (Lycan 1987, Tye 1995), others insisting on the nonrepresentational one (Block 1995, Chalmers 1996). For the anti-representationalists, the difference between a state that is conscious and one that is not is *not* a difference in how that state represents anything or a difference in the kind of representation it is or a difference in anything else representational. Since we will eventually come to raise some doubts about anti-representationalism, let us flag the view explicitly:

Anti-representationalism – the view that the difference between a state that is conscious and one that is not is not a difference in how that state represents anything or a difference in the kind of representation it is or a difference in anything else representational.

Here is how the anti-representationalist view can arise.

When something appears to us to be a certain way, the representation in which it appears that way can play two roles in our cognitive economy. On the one hand, the representation (or the contents of the representation) can connect inferentially to other representations: if the stick appears to have two straight parts with a bend in the middle, this will preclude representing it as forming a circle. The representation can also connect to belief: if the stick appears straight with a bend in it, we will not form a belief that it bends in a circle. And to memory: we can compare this stick as it appears to sticks I recall from the past. And action: if I want something to poke into a hole, I might reach for the stick. In all these cases, so long as I am *representing* the stick in the appropriate way, it would seem to be irrelevant whether I am *conscious* of the stick or not. My representation could do these jobs for me just as well even if I were not aware either of the stick or of my representation of it. But I am also *conscious* of the stick – it does *appear* to me in a certain way. This can easily seem to be something different from any representational properties of the representation, at any rate properties such as those we just considered.¹

¹ Chalmers' well-known (1995) distinction between what he calls the easy problem and the hard problem of consciousness starts from this distinction between the cognitive role of

Arguments for this conclusion often take the following form: the felt quality of a state could change while its representational properties remain the same. The arguments are usually based on thought experiments such as the inverted spectrum argument (how colours appear to us could be inverted without changing how our representations of colour function as representations) or the zombie argument (there could be creatures for whom it is not like anything to represent anything whose representations nevertheless function cognitively just as representations function in us).

Sometimes such arguments go so far as to conclude that what is distinctive to consciousness is not just not representational, it is not even physical. One way of arguing for this to make one's zombie a microphysical duplicate of conscious beings. If a zombie such as this is possible, then qualia are not a physical property of conscious beings. Another is Jackson's (1986) famous thought experiment concerning Mary, the colour scientist. Mary knows everything there is to know about the experience of colour, therefore everything *physical* there is to know about the experience of colour, but she has never experienced colour herself. Then she experiences colour. Clearly she gains something she did not have before. However, she knew everything physical about colour. Therefore, what she gains must be something nonphysical.

It is not clear that any of these thought experiments establish real possibilities, or, if they do, entail the conclusions drawn from them. For reasons of length, in this paper we will pass on that issue. Instead, we will turn to alternative approach to consciousness introduced earlier, the one found more often in the work of experimental psychologists.

The dominant approach in psychology

In sharp contrast to atomism and local realism (whether in its representational or its anti-representational form), the dominant approach to consciousness in experimental psychology holds that consciousness is a property of the cognitive system as a whole. Let us call it the *system approach to consciousness*:

System approach to consciousness – approaches to consciousness that view it as a property of whole cognitive systems, not individual or small groups of representations.

There is a great diversity of opinion as to what the relevant property is. We cannot begin to explore the whole range of options but here are a few examples. Baars (1988) holds that consciousness consists in a global workspace of a certain kind. Jackendoff (1987) urges that it is an

representations and something appearing to be like something in them.

intermediate level of representation, a phonetic or similar level between acoustic or visual input and full-blown conceptual content. Many theorists link consciousness very closely to attention. For example, Mack and Rock say that, "Attention [is] the process that brings a stimulus to consciousness" (Mack and Rock 1998), "if a ... percept captures attention, it then becomes an explicit percept, that is, a conscious percept" (Mack 2001, 2). Posner (1994) captures the spirit of this line of thinking about consciousness nicely:

an understanding of consciousness must rest on an appreciation of the brain networks that subserve attention, in much the same way as a scientific analysis of life without consideration of DNA would seem vacuous. [Posner 1994, 7398]

Nor is this approach without its philosophical allies. Dennett's (1991) multiple drafts model in which states become conscious by seizing control of cognitive resources is a similar approach. (Curiously, he says almost nothing about attention.) Paul Churchland is another example. Here is how Churchland summarized his approach recently:

[Consider] the brain's capacity to focus attention on some aspect or subset of its teeming polymodal sensory inputs, to try out different conceptual interpretations of that selected subset, to hold the results of that selective/interpretive activity in short-term memory for long enough to update a coherent representational 'narrative' of the world-unfolding-in-time, a narrative thus fit for possible selection and imprinting in long-term memory. Any [such] representation is ... a presumptive instance of the class of *conscious* representations. [Churchland 2002, 74]

This is a different conception of consciousness from the atomist one! Are there reasons to favour one over the other? There are. First reason: the systems approach has the potential to account for two kinds of consciousness, the atomist approach only one.

Two kinds of consciousness

The variety of different things that we can have in mind when we use the word 'consciousness' is a big topic, too big a topic to explore here. However, we can make one distinction fairly briefly and when we do, something quite interesting about the two approaches becomes apparent.

The distinction we have in mind is between consciousness of the world around us and consciousness of our own psychological states. Blindsight is sometimes invoked to illustrate this distinction but what is tendentiously called 'inattentional blindness' works better. (Tendentiously because there is actually a huge debate about whether the phenomenon in question has anything to do with attention [Mack, <http://psyche.cs.monash.edu.au/v7/psyche-7-16->

mack.htm].) In inattentional blindness research, the subject fixates on a point and is asked to note some feature of an object introduced at or within a few degrees of fixation. After a few trials, a second object is introduced, in the same region but clearly distinct from the first object. Subjects are not told that a second object will appear. When the appearance of the two objects is followed by 1.5 seconds of masking, at least one-quarter of the subjects and sometimes almost all subjects have no awareness of having seen the second object.

Yet – and this is what makes inattentional blindness better for our purposes than blindsight – when the second object is a word, subjects clearly encode it and process its meaning. Evidence? When asked shortly after to do, for example, a ‘stem completion task’ (i.e., to complete a word of which they are given the first two or three letters), they complete the word in line with the word they claim not to have seen much more frequently than controls do. In short, in inattentional blindness, subjects’ access to the word they are not aware of seeing is nevertheless very deep-running.

In inattentional blindness, it is important to note, objects *appear* in a certain way to the subject, as is evidenced by the subject processing semantic information provided by it.² What we have here is not merely Block’s A-consciousness, “a state ... poised for direct control of thought and action” (Block 1995, 233). The access to the unattended object is Block’s -consciousness or something very much like it: the object actually appears to the subject. (Note that if this claim is correct, it poses a considerable problem for attention theories of consciousness – something else we don’t have space to go into.) In these or similar cases of access without attention, subjects can, for example, point to the items in question. The objects can increase the subject’s level of alertness, especially the level of alertness concerning the objects themselves. And ensuing behaviour is often appropriate, not to the way the object actually is, but to how the objects looked to the subject (Dennett, 1978). Let us call the kind of consciousness that can be present in cases of inattentional information access and so on *consciousness of the world*. By contrast, let us call the consciousness that we have when we are *conscious* of representing items in the world

consciousness of self.³

Consciousness of the world – the kind of consciousness that can be present in cases of inattentional information access and so on

Consciousness of self – the consciousness that we have when we are conscious of representing items in the world

Now a reason for favouring the systems approach: all anti-representational versions of atomism and many representational versions (e.g., higher-order thought or experience models) have anything to say only about consciousness of self, the felt quality of psychological states, what it is like to have them, and cannot say anything about consciousness of the world, i.e., the way the world appears to someone. Systems approaches not only have something to say about consciousness of the world, they generally focus on it. When theorists talk about paying attention to something, for example, they generally have in mind paying attention to something in the world, not paying attention to one’s own states.

What a theory of consciousness must explain

A second reason for favouring a systems over an atomistic approach to consciousness: what a theory of consciousness actually needs to be able to explain.

If consciousness is a matter of things appearing – just appearing, in the case of consciousness of the world, consciousness that they are appearing in the case of (one kind of) consciousness of self –, then consciousness is a property of the activity of representing, not of individual representations. Consciousness is a matter of *something being conscious* of something. If so, an adequate theory of consciousness has to address the question: What is a *system* capable of consciousness like?

Here are some of the features of such a system:

- It is aware of whole groups of representations in one ‘act of consciousness’
- Often when it is aware of whole groups of representations, it is also aware of itself as the common subject of these representations.
- Its consciousness can be faint, full, etc.
- It has many global cognitive faculties and some of

². Change blindness, attentional blink, and visual neglect and the double dissociation between the ventral and the dorsal streams in the brain discovered by Milner and Goodale (1995) are related phenomena. In all these phenomena, information that the subject is not conscious of having nevertheless enters into cognitive tasks that use semantic information, disambiguation tasks, for example.

³. Consciousness of self needs to be broken down into consciousness of one’s psychological states and consciousness of oneself, the thing having those states. Moreover, there are radically different views afoot about what consciousness of one’s psychological states consists in. Some theorists even maintain that it is nothing more than consciousness of the world plus a shift of attention (Dretske 1995, Tye 1995). We have to ignore all these issues here.

them are closely linked to consciousness, memory, for example, or attention, or language.

- In particular, attention is closely linked to consciousness.
- For consciousness, a system simply having information as a result of representing this, that or the other is not enough; the system must make cognitive use of the information.
- Consciousness in a cognitive system can be independent of sensory inputs
- Its consciousness disappears in deep sleep, and . . .
- reappears in dreams.⁴

When faced with issues like these, the atomistic approach to consciousness has so far just clawed the air – and it is hard to think of circumstances under which it could do any better.

Take, for example, the unity of consciousness. Conscious subjects are aware at the same time, indeed in a single act of consciousness, of a great many items. A theory of the conscious subjects has to be able account for this unity.

The unity of consciousness comes in a number of kinds. Mental unity in general comes in at least six different kinds and four of them are kinds of unified consciousness:

1. unity of our cognitive elements (we can bring, for example, beliefs, desires, perceptions, intentions, and many other things to bear on a single situation);
2. unified consciousness of our world (we are aware of a whole host of things around us in a single, unified representation) and
3. unified consciousness of one's own representations;
4. unified consciousness of self (one is aware of oneself as the "single, common subject" of one's experience, as Kant put it),
5. unified focus of a number of cognitive resources on a single item of attention;

and,

6. unified behaviour (our behaviour is highly and multiply unified – think of a concert pianist playing a sonata).

Set items (i) and (vi) aside. Items (ii) to (v), the various kinds of unified consciousness, have a common core:

Unity of consciousness – a group of representations being related to one another such that to be conscious

of any of them is to be conscious of others of them and of the group of them as a single group.

Given how central unified consciousness is to the conscious mind, it is remarkable how little attention it has received in recent writings on consciousness, especially philosophical writings. Paul Churchland (1995, p. 209) includes it as one of his Magnificent Seven, the things that a theory of consciousness has to explain, and the notion is mentioned by a few other philosophers but in general it has received little attention (the topic and what has been done with it is reviewed in Brook 2000).

That consciousness is unified has immediate implications for atomism and local realism. If consciousness is unified, consciousness cannot be a property of single representations or tiny groups of representations (e.g., a representation and a thought directed at it on the HOT model) by themselves. Nor is it something that could fruitfully be studied by studying single representations in isolation. At present, we don't think that there is a theory of consciousness, representational or nonrepresentational, that provides an adequate account of the fact that consciousness is unified. To pay attention to it is to see the prospects for atomism about consciousness immediately plummet.

A Problem for the Systems Approach?

If the systems approach to consciousness seems more likely than atomism to be able to explain what a theory of consciousness has to explain, it also faces some problems. In particular, many theorists worry that it may leave out just the most crucial element, the consciousness itself. This worry arises in the following way. 'Surely', an objector will say, 'a cognitive faculties and capacities central to your favourite systems approach to consciousness could exist, and not only exist but function as they do, in the absence of consciousness?' This line of objection is the home of zombie thought-experiments: surely something could be just like us behaviourally, or (as in this case) functionally, or even physically, and yet not be conscious. All we can say here is that *if* zombie thought-experiments are coherent, then the systems approach is in trouble, as is every other representational theory of consciousness. But that is a big 'if'. Since the price of buying the idea that zombie thought-experiments are coherent is that consciousness has to be something deeply mysterious, maybe beyond cognitive ken altogether, we want to make very sure that zombie thought-experiments *are* coherent.

Adjudicating that issue and the background issue of the merits of anti-representational atomism vs. the systems picture of consciousness is a task for another occasion. Here we have merely tried to introduce the two approaches, lay out one reason to favour the systems approach, and look briefly at one difficulty it faces.

⁴ This list started from but goes beyond Churchland's list of the Magnificent Seven requirements on a theory of consciousness in (1995), pp. 213-14.

Abstract

We examined how naïve conversational participants circumscribed referential domains during the production and comprehension of referring expressions by monitoring participants' eye movements during a referential communication task. The results replicated some well-established results, e.g., incremental reference resolution, demonstrating the feasibility of studying real-time language comprehension in interactive conversation. We also observed a high proportion of underspecified referential expressions that were easily understood by addressees because of discourse and pragmatic constraints, including constraints developed as a result of the conversation.

Background

In characterizing work in language performance, Clark (1992) pointed out that the field has been largely divided into two traditions. One tradition, the language-as-action tradition, emphasizes interactive conversation as the most basic form of language use. According to this tradition the principles of language performance and language design cannot be understood without taking into account the interactive collaborative processes that are embedded in conversation. A central tenet in work within this tradition is that utterances can only be understood within a particular context, which includes the time, place and participant's conversation goals. Thus researchers within this tradition have focused primarily in investigations of interactive conversation using natural tasks, typically with real-world referents.

A second tradition, the language-as-product tradition, focuses primarily on the processes by which listeners decode (and speakers encode) linguistic utterances. Psycholinguistic work on language comprehension within in this tradition typically examines moment-by-moment processes in real-time language processing using fine-grained reaction time measures. The rationale for using these measures is that comprehension processes are closely

time-locked to the linguistic input which, for spoken language, unfolds over time. Until recently, the real-time response measures in the psycholinguist's toolkit required the use of de-contextualized language, typically pre-recorded sentences presented in impoverished contexts. This constraint ruled out real-time investigations of natural, interactive conversation. Moreover, a dominant theoretical perspective within the product tradition was that initial "core" processes (e.g., lexical access and syntactic processing) were informationally encapsulated from contextual influences (e.g., Fodor, 1983).

Recently, the advent of light-weight head-mounted eye-tracking systems has made it possible to investigate real-time comprehension in more natural tasks, such as tasks where participants follow spoken instructions to manipulate objects in a task-relevant "visual world" (Tanenhaus, Spivey-Knowlton, Eberhard & Sedivy, 1995). Fixations to task-relevant objects are closely time-locked to the unfolding utterance, providing a continuous real-time measure of comprehension processes at a temporal grain fine enough to track the earliest moments of lexical access, parsing and reference resolution (Tanenhaus, Magnuson, Dahan & Chambers, 2000).

A growing body of research employing eye-tracking techniques demonstrates clear effects of contextual constraints. For example, syntactic ambiguity resolution is influenced by referential constraints provided by the visual context, including the number of potential referents and their properties (Tanenhaus et al., 2000). Moreover, some recent work using confederates in constrained tasks suggests that under some circumstances information provided by knowledge of the speaker's perspective and intentions can affect even the earliest moments of comprehension (Hanna, 2001).

However, a major limitation of previous work is that all of the language used has come from scripted language, ruling out spontaneous collaborative processes that are likely to underlie circumscription of referential domains,

and interpretation of referential expressions in natural interactive settings. For example, Clark & Wilkes-Gibbs (1986) investigated conversational partners' use of collaborative processes to refer to low-codability shapes in a referential communication task (Krauss and Weinheimer, 1966). Pairs of participants worked together to arrange different abstract shapes. Over the course of the conversation they converged on shared names for the shapes, dramatically increasing the efficiency of their communication over the course of the interaction. In Brennan's (1996) words, conversational partners develop 'conceptual pacts' during the course of a conversation. The mere action of participating in the development of conversational pacts is essential for the increase in efficiency- overhearers privy to the entirety of the conversation and it's context are unable to perform as well in these natural tasks (Schober and Clark, 1989). These results suggest two things: 1) The act of participating in a natural conversation contributes to efficient communication. 2) Extracting conversational interaction from language comprehension removes a central component of natural language.

The goal of the present study was to explore the feasibility of examining real-time comprehension processes during natural, unscripted, interactive conversation. We focused on the comprehension of definite referring expressions, such as "the red block" and "the cloud". Definite reference provides an ideal domain for a first investigation for several reasons. First, definite reference is one of the most ubiquitous and central components of natural language. Second, use of definite reference assumes that a referent will be uniquely identifiable within a circumscribed referential domain. Much of the strongest evidence for the collaborative model of language processing comes from demonstrations that people collaborate to define referential domains. Third, work with restricted utterances has established two clear empirical results that allow one to track the time course of reference resolution: lexical competitor (cohort) effects and 'point of disambiguation' effects.

When listeners are instructed to pick up or move an object, such as a racket, fixations to the target object begin as early as 200 ms after the onset of the noun (Allopenna, Magnuson & Tanenhaus, 1998). Eye-movements launched at this point in the speech stream are equally likely to be directed to the eventual referent and other objects with names that are also consistent with the speech signal, such as a raccoon. However, looks to these competitors, hereafter "cohort" competitors are reduced or eliminated when context makes a cohort an implausible referent. Thus we can use cohort effects to infer the degree to which conversation restricts initial referential domains.

One of the most striking sources of evidence for rapid restriction of referential domains comes from point of disambiguation effects. For example, Eberhard, Spivey-Knowlton, Sedivy and Tanenhaus (1995) presented subjects with displays containing a variety of differently colored

shapes, as subjects listened to instructions such as "Click on the red triangle". In a subset of trials the color of the target item was not shared with any other items in the referential domain. In these trials the referentially disambiguating information was the color, which was conveyed in the prenominal adjective. In the remaining trials, the target item was the same color as another item in the referential domain. For example, the display accompanying the instruction "Click on the red triangle" might contain a red circle and a red triangle. In these trials the referentially disambiguating information came at the noun. Eye movements to the target were again closely time-locked to the speech. Looks to the target increased dramatically immediately following the point of disambiguation (POD), whether it came at the adjective or the noun.

In the present experiment we monitored eye-movements as pairs of participants, separated by a curtain, worked together to arrange blocks in matching configurations and confirm those configurations. The characteristics of the blocks afforded comparison with findings from scripted experiments investigating language-driven eye-movements, specifically those demonstrating cohort effects and incremental reference resolution. We investigated: (1) whether these effects could be observed in a more complex domain during unrestricted conversation, and (2) under what conditions the effects would be eliminated, indicating that factors outside the speech itself might be operating to circumscribe the referential domain.

Method

We tested four pairs of participants from the University of Rochester, who were paid for their participation in the study. The discourse partners each had an array of blocks and a board on which to place them. The boards were partially covered, creating 5 distinct sub-areas. Initially, sub-areas contained 56 stickers representing blocks. The task was to replace each sticker with a matching block. While partners' boards were identical with respect to sub-areas, partners' stickers differed: Every place that one partner had a sticker, the other partner had an empty spot. Pairs were instructed to tell each other where to put blocks so that in the end their boards would match. No other restrictions were placed on the interaction. The entire experimental study lasted approximately 2.5 hours. For each pair we recorded the eye movements of one partner, and the speech of both partners.

The initial configuration of the stickers was such that the color, size, and orientation of the blocks would encourage the use of complex noun phrases and grounding constructions. Nineteen of the stickers (and the corresponding blocks) contained pictures similar to those used by Allopenna, Magnuson and Tanenhaus (1998), in the study described above. We used a full-color version (Rossion & Pourtois, 2001) of a large corpus of normed pictures, balanced for their linguistic codability (Snodgrass & Vanderwart, 1980). We selected pairs of these pictures that referred to objects which had initially acoustically

consistent names (cohort competitors). Half of the cohort competitor stickers were placed such that both cohort competitor blocks would be placed in the same sub-area of the board, and half of the cohort competitor stickers were placed such that the cohort competitor blocks would be placed in different sub-areas of the board. All of the cohort competitor pairs were separated by approximately 3.5 inches. We examined the eye movements of one discourse partner with respect to the speech generated by the other discourse partner.

Results

The conversations for each of the four pairs were transcribed. We present eye-tracking analyses for two of the pairs; we are still analyzing the data from the remaining two pairs. The non-eye-tracked partner of each pair generated approximately 100-150 definite references to blocks during the course of the conversation. While the length of the conversation prevented us from initially analyzing more than 4 pairs, the large number of 'trials' generated by each pair gave us enough statistical power to circumvent this problem.

An ISCAN eyetracking visor was used (for details see Trueswell, Sekerina, Hill & Logrip, 1999). The image of the eye-tracked partner's board, and their superimposed eye position, along with the entirety of the conversation (both participants' voices) were recorded using a frame-accurate digital video recorder (a SONY DSR-30). Eye movements were analyzed at the onset of the definite reference, and continued 2000ms after the NP was complete. There was a high degree of variability in the length of utterances, especially those to color blocks.

References to blocks which had cohort competitors (approximately 75 references per pair) were expected to reveal similar cohort effects as observed in more restricted experimental paradigms. To our surprise, we observed only one look to a cohort competitors during both 2 1/2 hour conversations we have analyzed thus far. We do not think this null result is due to poor stimulus design, as we did observe looks to cohort competitors under special circumstances. Periodically, subjects needed to remove the eye-tracker to take a break. When we put the tracker back on and re-calibrated, we tested the calibration by asking the subjects to look at different items on the board. Under these circumstances the referential domain is not restricted by conversational constraints. Here we saw clear cases of subjects initially looking at the cohort competitor before looking at the intended referent.

Each pair provided us with approximately 75 trials of data for eye-movements elicited by definite references to colored blocks. Two researchers coded the definite NPs for their point-of-disambiguation, and resolved any coding differences. The POD was the point at which the NP uniquely identified a referent, given the visual context at the time. Average POD was 858ms (26 frames) following NP onset. Eye-movement analyses for NPs with a unique linguistic point of disambiguation (50%) were analyzed

separately from those which were never fully disambiguated linguistically. The eye-tracking analysis was restricted to cases where at least one competitor block was present. As a result, the number of ambiguous trials used for the analysis was close to 50, while there were only approximately 20 for the disambiguated trials.

Eye-movement analyses (planned comparisons) were performed on 800ms epochs for both ambiguous and disambiguated NPs. Eye movements elicited by disambiguated references showed clear point of disambiguation effects; within 200ms of the disambiguation point, looks converged on the target block: we found a main effect of condition $F(2,20) = 64.03$, $p < .0001$, and Bonferroni post-tests revealed significantly more looks to the 'target' than 'competitor' and 'other' unrelated blocks. (see Figure 1). Before the disambiguation point, subjects were looking equally at the target and competitor block(s), the main effect of condition, $F(2,19) = 6.77$, $p < .01$, was due to significantly more looks to target than other blocks ($p < .001$); looks to target and competitor were equivalent at this region. At the 522ms baseline region (-1122 to -600ms) there was no effect for condition. This replicates the point-of-disambiguation effect seen by Eberhard, et al. (1995), demonstrating that we were successful in using a more natural task to investigate on-line language processing. Upon inspection of the eye-movement plot, one should note that we do observe a pre-POD target bias. We will argue that this initial bias is due to additional pragmatic constraints that are operating during the task.

Figure 1: Proportion of fixations to Targets, Competitors, and Other blocks by time (ms) for Disambiguated NPs. Graph is centered by item with 0 ms = POD onset.

Most remarkably, ambiguous utterances elicited significantly more looks to the target than unambiguous utterances (see Figure 2). Moreover, fixations were primarily restricted to the referent shortly after onset of the definite reference; we observed significantly more looks to targets than competitors within the first 200 ms of NP onset, a significant effect of condition, $F(2,53) = 18.37$, $p < .0001$, was due to significant differences between target and both

competitor and other blocks ($p's < .0001$). This effect persisted in the second 800ms window.

Figure 2. Proportion of fixations to Targets, Competitors, and Other blocks by time (ms) for Ambiguous NPs. Zero ms = NP onset.

These results suggest that 1) speakers systematically use less specific utterances when the referential domain has been otherwise constrained; 2) the attentional states of speakers and addressees become closely tuned; and 3) utterances are interpreted with respect to referential domains circumscribed by contextual constraints.

In order to identify the factors that led speakers to choose underspecified referring expressions, and that enabled addressees to understand them, we performed a detailed analysis of all of the definite references.

Recency is one factor that is likely to influence the form of a referring expression, with the most recently mentioned entity being more salient than other (non-focused) entities. (We are assuming that references to the most focused entity would typically result in use of a pronoun, a hypothesis that we are currently evaluating in the data set.) Thus, recency of last mention of the target block should predict the degree of specification, with references to the most recently mentioned block of a type, resulting in ambiguous referring expressions. For example, if "the green block" is uttered in the context of a set of 10 blocks, 2 of which are green, 'recency' would predict that the referent should be to the green block that was most recently mentioned. Indeed, this is what we found: Ambiguous utterances were more likely to refer to the most recently mentioned block of its type, while this effect was the opposite for Disambiguated utterances. This effect was substantiated by a significant chi-square for independence, $\chi^2=7.389$, $p=.01$.

While recency of mention is clearly an important factor constraining interpretation of ambiguous references, approximately 36% of these references did *not* refer to the most recently mentioned block. Additionally, the recency analysis alone does not explain why speakers sometimes chose to fully specify a reference when referring to the most recently mentioned block of its type; in fact 30% of

disambiguated utterances referred to the most recently mentioned block of its type. Two questions arise from these observations: 1) Why are addressees not confused when a speaker uses an underspecified expression to refer to something other than the most recently mentioned thing; 2) What factors determine when speakers will add extra information when referring to the most recently mentioned block?

In answer to the first question, we propose that additional pragmatic and task-based factors function to constrain the referential domain, allowing speakers to underspecify, addressees to interpret ambiguous references, and may explain the early target advantage in the disambiguated trials. In addition to recency of mention, we identified three factors which contributed to the intelligibility of referring expressions: 1) Proximity of target referent to the last mentioned block; 2) Task-based constraints (such as limitations on block placement due to the size and shape of the board); 3) Spatial Terms which focus attention to a subset of the work area. We are currently performing a detailed analysis of the interaction of these constraints, and a comparison of how the predictions made by the constraints compare with the predictions of the addressee.

Finally, analysis of the eyetracking data of the final two pairs will allow us to do a sub-analysis of the eye-movements during trials influenced by these different factors. Our hypothesis is that both linguistic factors (such as recency of mention) in addition to pragmatic factors (such as proximity and task constraints) are contributing to the ease with which subjects are identifying the intended referents of these ambiguous references.

The answer to the second question, is the reverse of the answer to the first. We would like to suggest that in cases where confusion is high, conversation is inefficient, or these additional task and pragmatic constraints may select the *wrong* referent, speakers may choose to add additional disambiguating information. In order to verify this claim, we intend to compare the referential domain circumscribed by these additional constraints, with the intended referent of the speaker. We predict that a mismatch would lead to an increase in the likelihood of extra disambiguating information.

As a part of this analysis, we have also looked at the cases in which speakers overdisambiguate. In approximately 21% of the disambiguated utterances, speakers added between 1 and 3 additional elements past the POD. In the following example, the reference was disambiguated at 'long', yet the speaker chose to continue: "the long green square that was laying down". This speaker added two extra elements, a color term, and a collaboratively defined term, which means 'horizontal'. In many cases, the speaker spent a relatively large amount of time uttering extra disambiguating information, especially lengthy collaborative terms (Collaboratively-defined terms were common in this corpus; approximately 20% of ambiguous and 40% of disambiguated references contained collaboratively-defined terms). Of the overspecifying elements used, only 50% were

color terms, which are the prototypical overdisambiguating element. The other 50% included references to previous actions, the location of the object and its shape. In general, speaker overspecification may be for clear communicative purposes, rather than as a bi-product of the production system.

Conclusions

In this experiment, we investigated 1) whether it is possible to observe incremental processing effects in a complex domain during unrestricted conversation, and 2) under what conditions these effects might be absent, indicating factors outside the speech itself might be operating to circumscribe the referential domain. We were successful on both counts. We did observe incremental reference resolution in certain contexts, and in the contexts in which it was not observed we were able to identify a number of constraints that seemed to be operating to circumscribe the referential domain. These constraints included linguistic recency, pragmatic factors related to the task itself, such as physical limitations on block placement due to the size and shape of the board, and proximity of a given referent to a previously mentioned block. An example of a segment of the discourse in which recency circumscribes the referential domain is shown below:

- 2. ok. RIGHT directly next to the cloud?
- 1. mm-hmm
- 2. just throw in a red piece, line it up evenly
- 1. just a red, little *square*
- 2. yup
- 1. k, got it
- 2. ok
- 1. now, I got an easy one, so I wanna *give it* to you
- 2. *ok*
- 1. directly...ABOVE the red, grab your lamp

The first description of the target block (underlined) is unambiguous, but the second reference to the block is ambiguous given the visual context (there are 5 other red blocks in that sub-area of the board). Listeners do not have difficulty with the linguistic ambiguity in this situation because they take recency into account, unifying the referents of the two referring expressions. An example of a segment of the discourse in which task constraints circumscribe the referential domain is shown in below:

- 1. ok, you're gonna line it up... it's gonna go <pause> one row ABOVE the green one, directly next to it
- 2. can't fit it
- 1. cardboard?
- 2. can't yup, cardboard
- 1. well, tell it too back
- 2. the only way I can do it is if I move, alright, should the green piece with the clown be directly lined up with thuh square?

Again, the referring expression (underlined) is ambiguous given the visual context. In this case the listener does not have difficulty dealing with this ambiguity because, although there are a number of blocks one could line up with "the green piece with the clown", only one is task-

relevant. Given the location of all the blocks in the relevant sub-area, the target block is the easiest block to line up with the clown. The competitor blocks are inaccessible because of the position of the other blocks or the design of the board. An example of a segment of the discourse in which proximity constrains the referential domain is the following:

- 2. ok, so it's four down, you're gonna go over four, and then you're gonna put the piece right there
- 1. ok...how many spaces do you have between this green piece and the one to the left of it, vertically up?

As before, the referring expression (underlined) is ambiguous given the visual context; there are approximately five blocks up and to the left of the previously focused block (the one referred to in the NP as "this green piece"). In this case the listener does not have difficulty dealing with the ambiguity because he considers only the block closest to the last mentioned block ("this green piece"). Finally, an example of a reference that is constrained by a spatial term is underlined in the following exchange:

- 2: ok, and then...alright, so then there is a dark green one? to thEE uh northeast of that green one?
- 1: yup
- 2: and, um, they're only overlapping...one...line and then there's a yellow one...below the dark green one that I just talked about and to the l- to the RIGHT of the other dark green one.

The underlined reference is constrained before the onset of the noun phrase by the spatial terms used before it (bolded). When the listener hears the target noun phrase, she is already aware that the referent is **below** 'the dark green one', and that there is a space to the left of it (as she is directed to place a yellow block **to the right** of the referent). This information narrows the interpretation of the reference down to a single block, whereas the reference was otherwise ambiguous with respect to that sub-area in general.

We are currently detailing the predictions of and the interactions between these different constraints and the degree to which they predict both speaker behavior, and the interpretation processes of the addressee. Our observations and analysis of incremental interpretation during this task suggest a view of language processing in which conversational participants coordinate a mutually aware reliance on certain discourse, pragmatic and task based constraints which facilitate efficient completion of the task at hand. Our data mark an important first step towards being able to rigorously analyze the on-line processing of interactive conversation 'in the wild'. To our knowledge, this is the first demonstration of on-line circumscription of referential domains in a natural interactive task with naïve participants. As we continue to develop more explicit models of on-line language processing, a critical part of this process should be to inform these models with observations made in these natural situations. Pairing methodologically rigorous laboratory studies with naturalistic studies such as this one is essential to an understanding of language processes that is both detailed, and ecologically valid.

To conclude, we successfully replicated a standard psycholinguistic effect, the point of disambiguation effect, in unscripted interactive conversation with naïve participants. We also obtained results suggesting that reference selection and comprehension is modulated by both discourse-based factors, such as recency, but also by task specific pragmatic constraints.

Moreover, reference resolution appeared to be affected by collaborative constraints that developed during the conversation. Our participants spontaneously created collaborative terms for troublesome words (such as 'horizontal' and 'vertical'), and tuned their utterances, and comprehension systems for such details as the recency of mention of each particular kind of block, proximity of blocks to one another, and task constraints idiosyncratic to our block-game. These observations suggest that the attentional states of the speaker and listener become closely tuned during the course of interaction. An important question for future research is how these factors differentially affect speakers and addressees. The data that we have collected is rich enough to allow us to investigate this and other questions.

On Straight TRACS: A baseline bias from mental models

Kevin Burns (kburns@mitre.org)

The MITRE Corporation, 202 Burlington Road
Bedford, MA 01730-1420 USA

Abstract

TRACS (Tool for Research on Adaptive Cognitive Strategies) is a family of games played with a special deck of two-sided cards (see www.tracsgame.com). TRACS has the advantage of being both mathematically tractable to theoretical analysis and psychologically relevant to practical applications. The simplest game, called Straight TRACS, is a series of choices where the player must turn over one of two cards to match a third card. The object is to make the most matches on a trip through the deck. The challenge is to track the changing odds in order to make the best choices. We performed experiments and simulations to measure human performance in this probabilistic and dynamic task. We present our finding of a Baseline Bias, in which subjective odds are (incorrectly) anchored to the baseline odds. This is an interesting result because it is contrary to other well-known biases, such as Gambler's Fallacy, in which subjective odds are (incorrectly) not anchored to the baseline odds. We propose a theory of mental models to reconcile our finding with previous research on heuristics and biases.

Introduction

A dilemma of decision research is to obtain the rigors of controlled experimentation yet maintain some relevance to practical applications. Our approach is a synthetic task environment (Gray, in press) called "TRACS" (Burns, 2001a) that replicates the cognitive challenges of naturalistic decision-making (Klein, 1998), including probabilistic risk assessment and dynamic resource allocation.

TRACS is both a unique game and a useful tool (Burns, 2001b). From a mathematical perspective, TRACS is unique because it is played with a special deck of two-sided cards, and because it has extensible rules that allow the same game to be played alone or with others.

Unlike standard playing cards, the backs of the cards provide clues to the fronts, and the deck contains unequal numbers of each card type (Table 1). Compared to Poker and other games of imperfect information, the two-sided cards make TRACS more tractable to theoretical analysis of optimal solutions. Compared to Chess and other games of perfect information, the two-sided cards make TRACS more relevant to diagnoses and decisions in practical domains like business, medicine and warfare.

From a psychological perspective, TRACS is useful because it provides a naturalistic micro world for experiments and simulations. Unlike other approaches to research on probabilistic reasoning, which often employ verbal stimuli in the form of static questions, TRACS employs graphical stimuli in a game of dynamic situations. This reduces artificial framing effects (see Nickerson, 1996) and introduces realistic temporal context.

We are using TRACS to perform experiments on human subjects and to perform simulations with software agents. Our experiments are designed to elicit cognitive strategies and our simulations are designed to evaluate these strategies against normative standards. Taken together, our experiments and simulations allow us to build and test models of cognitive competence that are relevant to practical applications in command and control (Burns, 2001c).

This paper reports on our first experiment and simulations using the simplest version of the game, called Straight TRACS. We explain the game, discuss our experiment and present our finding of a Baseline Bias. We also propose a theory of mental models to reconcile our finding with previous research on heuristics and biases.

The Game

Straight TRACS is a solitaire game played with 24 two-sided cards (Table 1). The backs of the cards, called "tracks", show black shapes (triangle, circle or square). The fronts of the cards, called "treads", show colored sets (Red or Blue) of these same shapes. Table 1 shows the distribution of shape/color (track/tread) cards in the deck. This distribution defines the baseline odds. For example, at the start of the game, a triangle track is likely ($6/8 = 75\%$) to be Red, a square track is likely ($6/8 = 75\%$) to be Blue and a circle track is 50-50. However, during the game, the odds change as the deck is depleted.

Table 1: Distribution of cards in the deck. The backs are called "tracks" and the fronts are called "treads".

# of Cards	6	4	2	2	4	6
Front (tread)	Red	Red	Red	Blue	Blue	Blue
Back (track)	▲	●	■	▲	●	■

To play Straight TRACS, the deck is held face down and three cards are dealt to a field. Two cards are dealt face down (showing their tracks) and the third card is dealt face up (showing its tread). The player's task is to turn over one of the two tracks (revealing its tread), trying to match the tread (color) of the third card. The turn is scored a "save" if the treads match or a "strike" if the treads clash. The two treads are removed from the field and the remaining track is turned to reveal its tread. This becomes the tread to match on the next turn. Two new tracks are dealt from the deck, a track is turned, the treads are scored, etc. Play continues until all cards (except the last two, which do not count) have been paired and scored. The object of the game is to minimize strikes on a trip through the deck.

Experiment

The goal of our experiment was to measure how people track the changing odds in TRACS. The probe in our experiment was a confidence meter that players set before each turn to indicate their subjective belief in the color (tread) of each shape (track) on the field. We used two different confidence meters (Figure 1), both based on a spectrum that runs from 100% Red to 100% Blue. One confidence meter displayed a discrete set of qualitative values on an octal scale. The other confidence meter displayed a continuous set of quantitative values on a decimal scale.

Figure 1: Two different confidence meters.

We tested 43 adults playing 10 games each. Subjects were tested on a personal computer using a mouse to set the confidence meter. There were no time limits, but each game was typically completed in less than 5 minutes. Each subject played in two blocks of 5 games, one block with each confidence meter in balanced design to control for fatigue and learning effects. The two blocks were separated by a short break. Before data collection, subjects read a playbook that described the cards and rules, watched a demo and played a practice game. All games were played with random shuffles of the deck and all $43 \times 10 = 430$ shuffles were unique. The experimental results were similar for Button and Pointer confidence meters, so all data is combined here, rounding Pointer data to the nearest Button for consistency.

Analysis

Baseline Bias

The player's problem is illustrated in Figure 2, which shows the actual odds for a typical game. By convention, we measure odds in % Red, where % Blue = $100 - \% \text{ Red}$. Figure 2 shows that the odds for each track type start at their baseline values (75% Red for triangles, 50% Red for circles and 25% Red for squares). However, the actual odds change (moving up/down on Figure 2) as tracks are turned to reveal their treads (moving right on Figure 2).

Figure 2: Change in actual odds (typical game).

Figure 3 illustrates a typical player's solution to the problem illustrated in Figure 2, as reported by the player's setting of the confidence meter for each track (before each turn). Relative to the actual odds (Figure 2), we see that the reported odds exhibit a bias towards the baseline odds. For example, after a minor adjustment near the start of the game, the player (Figure 3) reported constant odds for circles even after the actual odds (Figure 2) had moved far from the baseline. This Baseline Bias is explored further below.

Odds Inversions

Recall that the object of Straight TRACS is to turn the track that is most likely to match a given tread. At the start of the game, this is a simple task since the baseline odds specify which track to turn, e.g., triangle rather than circle to match Red. However, as the deck is depleted, the actual odds for two track types may become "inverted" with respect to their baseline configuration. This occurs whenever there is a crossover of two track types on the dynamic odds plot (Figure 2).

Figure 3: Change in reported odds (typical game).

For example, in Figure 2, a crossover near the middle of the game causes the odds to be less % Red for triangles than for circles for the remainder of the game. This is an inversion of the baseline odds relation between triangles and circles. Figure 3 shows that the player failed to detect this odds inversion.

As a gross measure of cognitive competence, we treat each odds inversion as a signal that a player must detect in order to minimize strikes in Straight TRACS. Figure 4 shows the total number of hits, misses and false alarms for this signal (for all players and all games). The relatively small number of hits compared to misses demonstrates that subjects exhibit a Baseline Bias. The occurrence of some hits and false alarms suggests that, although biased towards the baseline odds, subjects are at least trying to update odds, i.e., they are not just playing the baseline odds.

Figure 4: Detection of odds inversions.

Average Error

Each odds inversion (see above) involves a pair of tracks. As another measure of cognitive competence, we also examine confidence errors for single tracks. Figure 5 shows the average error versus turn in game, for human subjects and for a simulated agent that always plays the baseline odds.

Figure 5 shows that error increases with turn, i.e., as the actual odds deviate more from the baseline odds, for both the human subjects and the baseline agent. This shows that people have a Baseline Bias relative to the actual odds (zero error). Figure 5 also shows that the average error is higher for human subjects than for the baseline agent at the start of the game. This is a surprising result because: (1) The baseline odds are explicitly illustrated on the cards (treads) for the player to see. (2) The actual odds are obviously equal to the baseline odds at the start of the game. (3) Playing the baseline odds is a strategy that requires virtually no mental effort.

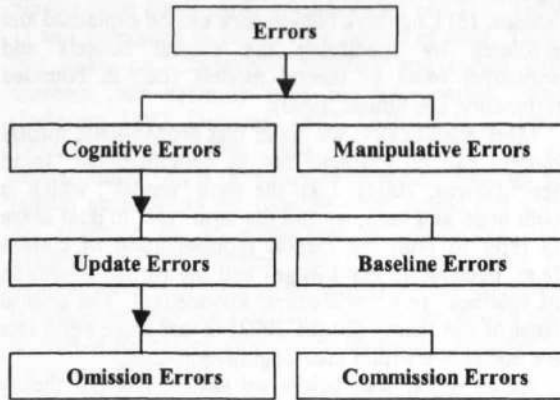

Figure 5: Average error in reported odds.

Kinds of Errors

To help explain Figure 5, we define a taxonomy of errors (Table 2). We first distinguish between Cognitive Errors, which are mental errors in judging odds, and Manipulative Errors, which are physical errors in moving the mouse to match the mind. We then distinguish between two kinds of Cognitive Errors: Update Errors are mental errors in updating odds relative to baseline odds, and Baseline Errors are mental errors in estimating the baseline odds themselves. Finally, we further distinguish between two kinds of Update Errors: Omission Errors are where no mental update is performed when it should be, and Commission Errors are where a mental update is performed but the result is incorrect.

Table 2: A taxonomy of errors.

The baseline agent makes no Manipulative Errors, no Baseline Errors and no Commission Errors, i.e., it makes only Update Errors of Omission. In fact, since the baseline agent never updates odds, its performance provides an upper bound on the magnitude of Omission Errors. Figure 5 shows that the baseline agent's Update Error is non-zero on turn 1. This is because the tread on the first field can cause a change in odds before the first turn. For example, assume that the cards on the first field are circle (track), Red circle (tread) and square (track). The baseline odds for circles are 4/8 Red, but since one Red circle is revealed as a tread on the field, the actual (updated) odds for circles are 3/7 Red. The same effect is magnified on later turns as more treads are revealed, hence the Omission Error increases with turn (Figure 5, curve for baseline agent).

For human subjects, the total error comprises Manipulative Error, Baseline Error and Update Error (Omission and Commission). The difference between total human error and baseline agent error on turn 1 is attributed to Manipulative Error and Baseline Error, which we assume are relatively independent of turn in game. Thus, the curve for total human error can be shifted downwards (curve * in Figure 5) to get an estimate of human Update Error.

This shifted curve for human error is directly comparable to the error curve for the baseline agent, which also includes only Update Error. The comparison (Figure 5) shows that human subjects are biased towards the baseline agent, relative to the actual odds (zero error). However, the shifted curve also shows that human subjects outperform the baseline agent (who does not update odds), and the difference grows with turn as the difference between actual odds and baseline odds increases. Thus, we conclude that human subjects make fewer Omission Errors than the baseline agent, and that the Commission Errors made by human subjects are not significantly larger in number and magnitude than the baseline agent's Omission Errors.

Anchoring and Adjustment

These results are consistent with the well-known heuristic strategy of "anchoring and adjustment" (Tversky & Kahneman, 1974). In our case, the baseline odds (with some Baseline Error, see above) are the anchor to which people make adjustments. The adjustments are, on average, better than pure anchoring but significantly worse than optimal adjusting.

To gain further insight into the adjustments, we examine how the confidence meter settings change from turn to turn (for the same track type). We define various magnitudes of adjustment (i.e., no-button jump, one-button jump, two-button jump, etc.) and compute the number of times each magnitude of adjustment was made. Figure 6 compares the results for human subjects to an optimal agent (playing the same games) who always sets the confidence meter at the actual odds. As expected from anchoring, human subjects most often make a no-button adjustment. This is in contrast to the optimal agent, who most often makes a one-button adjustment.

Figure 6: Number of adjustments (by magnitude).

Besides the magnitude of adjustment, we also examine various types of adjustments. We define five types of adjustments (Table 3) and compute the number of times each type of adjustment was made. Figure 7 compares the results for human subjects to an optimal agent (playing the same games) who always sets the confidence meter at the actual odds.

Table 3: Types of adjustments (anchor = baseline odds).

Type 0	No adjustment
Type 1	From on-anchor to off-anchor
Type 2	From off-anchor to more off-anchor
Type 3	From more off-anchor to less off-anchor
Type 4	From off-anchor to on-anchor

As expected from anchoring, Figure 7 shows that human subjects make many more Type 0 adjustments (actually non-adjustments) and less Type 1 and Type 2 adjustments than the optimal agent. Figure 7 also shows that the difference between Type 1 and Type 4 adjustments is smaller for human subjects than for the optimal agent. This suggests that, when people do move off the baseline anchor (Type 1) in an attempt to adjust odds, they often “lose it” and return to the baseline anchor (Type 4). The optimal agent moves off the baseline anchor (Type 1) more often and returns to the anchor (Type 4) only when the actual odds are equal to the baseline odds (i.e., the agent never “loses it”).

These results (Figures 6 and 7) further support our conclusion that Baseline Bias in TRACS (Figures 4 and 5) is caused by a heuristic strategy of anchoring and adjustment.

Figure 7: Number of adjustments (by type).

The question, of course, is how (exactly) do people decide when and how much to move off anchor? That is, what (exactly) are the mental limits that prevent more accurate adjustments? The answer is crucial if we are to explain and predict human performance in TRACS or any other domain where people must think probabilistically about things that are changing dynamically. Below we propose a theory of mental models that takes a first step in this direction.

Theory

Mind Sets

We claim (Burns, in press; 2002; 2001b; 2001c; 2001d) that people make sense of the world by forming probabilistic models in their heads (see Knill & Richards, 1996; Johnson-Laird, 1994; Gigerenzer et al., 1991).

We further claim that: (1) Mental models are bounded by natural regularities of the world. (2) Mental models have a normative basis within their natural bounds. (3) Cognitive competence can be explained and predicted by specifying the natural bounds and normative basis of mental models (i.e., in bounded rationality, see Simon, 1990).

More specifically, we claim that probabilistic mental models can be characterized as computational “mind sets” (Burns, 2002). Like the term “model”, which is both noun and verb, we use the term “set” in dual sense to refer to both the mental representation of classes (e.g., declarative knowledge) and the mental operation of routines (e.g., procedural knowledge). The central tenet of our theory (Burns 2002) is that these mind sets are normative within their cognitive bounds.

As an initial test, below we sketch how our theory can explain Baseline Bias in TRACS. We also sketch how our theory can reconcile Baseline Bias with previous findings of Gambler’s Fallacy and Base Rate Neglect in other probabilistic reasoning tasks (Tversky & Kahneman, 1974). This is a non-trivial test of the theory, since Gambler’s Fallacy and Base Rate Neglect appear at first glance to be contrary to Baseline Bias.

Gambler’s Fallacy and Base Rate Neglect

In Baseline Bias (in TRACS), people do not update the baseline odds when they should. Conversely, in Gambler’s Fallacy, people update the baseline odds when they should not. Furthermore, in Base Rate Neglect, people discount or ignore the baseline odds altogether. How can we explain these differences? According to our theory, all three biases occur because people reason about probabilities with mind sets.

For Base Rate Neglect (Tversky & Kahneman, 1974; Koehler, 1996; Cosmides & Tooby, 1996), we suggest that people ignore the baseline odds in light of other evidence because they believe that the baseline odds reflect a less relevant (not applicable) set of occurrences. It is difficult in theory, let alone in practice, to aggregate probabilities that are derived from diverse sources with different pedigrees. As such, it is a bounded-Bayesian strategy to rely on the one source that is judged to be most relevant and reliable. Base rates that are judged irrelevant or unreliable are therefore neglected.

For Gambler’s Fallacy (Tversky & Kahneman, 1974), we suggest that people update the baseline odds because they are judging odds for a finite (bounded) set rather than for an infinite set. For example, after seeing 10 heads and 2 tails, a gambler who believes the coin is fair will think that the future holds more tails than heads, simply because he thinks that the eventual (large but finite) set of many tosses for this coin will be balanced. As such, it is a bounded-Bayesian inference to conclude that the future odds are slightly higher for tails than for heads.

For Baseline Bias (in TRACS), we suggest that people want to update odds (as they tell us) but that it is simply beyond their cognitive capacity. To do so, players must count cards in each of six sets (see Table 1) and normalize to convert the counts to odds. These two tasks, i.e., concurrent counting and normalizing numbers, are naturally hard for the unaided mind (Dehaene, 1997; Dehaene, 1992; Gallistel & Gelman, 1992; Nickerson, 1996). Thus, with self-knowledge of mental limits, it is a bounded-Bayesian strategy to remain anchored to the baseline odds unless and until the evidence for an adjustment is compelling. For example, in the extreme case, pure anchoring to baseline odds (i.e., never adjusting) is the bounded-Bayesian strategy for a decision maker who knows that he cannot remember which cards have been revealed in the course of a game.

Conclusion

Our initial experiment and simulations show that TRACS provides a useful micro world for investigating how people make diagnoses and decisions under uncertainty. Our finding in Straight TRACS is that players exhibit a Baseline Bias, which we attribute to a heuristic strategy of anchoring and adjustment. We sketched a theory of set-based mental models that reconciles our finding with previous research on heuristics and biases. Our future plans are to use TRACS to investigate the mental limits of concurrent counting, normalizing numbers and other facets of cognitive competence in probabilistic and dynamic reasoning.

Contradictions and Counterfactuals: Generating Belief Revisions in Conditional Inference

Abstract

Reasoners revise their beliefs in the premises when an inference they have made is contradicted. We describe the results of an experiment that shows that the belief they revise depends on the inference they have made. They revise their belief in a conditional (if A then B) when they make a modus tollens inference (from not-B to not-A) that is subsequently contradicted (A). But when they make a modus ponens inference (from A to B) that is contradicted (not-B) they revise their belief in the categorical assertion (A). The experiment shows that this *inference contradiction effect* occurs not only for factual conditionals but also for counterfactual conditionals. However, reasoners revise their beliefs in factual conditionals more than counterfactuals.

Belief Revision

Suppose you know the following well-established set of knowledge to be true:

If the car was out of petrol then it stalled.

The car was out of petrol.

What, if anything, follows?

You may conclude:

The car stalled.

But suppose additional knowledge comes to light at a later time and you discover the following is true:

The car did not stall.

What do you think you should believe to be true at this point?

New information can contradict previously held beliefs and inferences about the world. The ability to recognise inconsistency is a necessary step in revising beliefs (e.g., Legrenzi, Girotto, & Johnson-Laird, 2002). Once inconsistencies and contradictions are detected, they must be resolved (e.g., Elio & Pelletier, 1997). For example, you may decide to revise your belief in the conditional, and believe instead that the car being out of petrol does not necessarily mean that it stalled (it may be a diesel engine). Or you may revise your belief in the categorical, and believe instead that the car was not entirely out of petrol.

Dealing with contradictions is common not only in scientific discovery but also in everyday 'non-monotonic' inference. Which beliefs do people revise most readily? Conditionals can convey explanations, regularities or hypotheses about the world; categoricals can convey facts, data or observations (Elio, 1997). Revising the conditional or categorical is equally acceptable logically (Revlín, Cate, & Rouss, 2002). Yet most studies show that reasoners revise their belief in the conditional (Dieussaert, Schaeken, De Neys, & d'Ydewalle, 2000; Elio, 1997; Elio & Pelletier, 1997; Politzer & Carles, 2001; Revlin, et al, 2002).

Reasoners may prefer to revise some sorts of beliefs more than others because they accommodate new information by changing little of their existing beliefs (Harman, 1986). Minimal changes can be accomplished by altering beliefs that have the least explanatory power or informational content (Gärdenfors, 1988). Categoricals convey more semantic information (they rule out more states of affairs as false) than conditionals (Johnson-Laird & Byrne, 1991); but conditionals and categoricals may differ in how entrenched they are in a belief system.

Intriguingly, some studies suggest that the belief reasoners revise depends on the inference contradicted.

Consider a second problem:

If the car was out of petrol then it stalled.

The car did not stall.

You may conclude:

The car was not out of petrol.

But suppose the additional knowledge comes to light:

The car was out of petrol.

What do you think you should believe to be true? Once again you may decide to revise your belief in the conditional; or you may revise your belief in the categorical, and believe instead that the car did stall. The first example illustrates a modus ponens inference and the second illustrates a modus tollens inference, and Table 1 summarizes the structure of the two sorts of problem.

Table 1: Two types of belief revision problem

	Modus ponens	Modus tollens
1. Conditional	If A then B	If A then B
2. Categorical	A	Not-B
3. Conclusion	B	Not-A
4. Contradiction	Not-B	A

The Inference Contradiction Effect

Some studies show that reasoners revise their belief in the conditional more when a modus tollens inference has been contradicted, whereas they revise their belief in the categorical more when a modus ponens has been contradicted (Elio, 1997, experiment 1; Politzer & Carles, 2001). The possibility that the belief reasoners revise depends on the inference that has been contradicted, which we will call the *inference contradiction effect*, is puzzling. The contradiction establishes the same counterexample for both inferences, e.g., the car was out of petrol and it did not stall (A and not-B), yet the counterexample is accommodated differently in each case.

However, it is by no means clear whether an inference contradiction effect exists: some studies show the opposite pattern (Dieussaert, et al, 2000; Revlin, et al, 2002), and others show more revision of the conditional following a modus ponens inference, but equal revision of the categorical following modus ponens and tollens (Elio & Pelletier, 1997). The vagaries may arise because previous studies have asked participants to select from different sorts of - sometimes quite complex and constrained - options, e.g., to indicate denial or doubt about each of the statements, to choose one statement to reject, to rate degrees of belief, or to choose among various compound options such as 'disbelieve conditional and uncertain about categorical'. Our aim in the experiment we report is to establish whether an inference contradiction effect exists, and so we allowed participants to generate their own revisions, unfettered by pre-set selection options.

Previous studies have also presented a conclusion to participants prior to contradicting it, without requiring participants to indicate their evaluation of the inference. A participant who has not made the inference, or who does not agree that the presented inference is valid, may not need to engage in belief revision following the subsequent 'contradiction'. To guard against such a possibility, we allowed participants to generate the inferences they considered to follow from the premises, prior to presenting them with a contradiction, and in this way we ensured that their beliefs were genuinely contradicted.

Our conjecture is that an inference contradiction effect occurs because different cognitive processes are required to alter conditional and categorical beliefs following modus ponens and tollens inferences, and we return to this idea after we consider some new data.

Generation of Belief Revisions

We constructed a set of 8 problems, consisting of three modus ponens inferences, three modus tollens inferences, and two fillers based on quantifiers. The problems were based on a science fiction content about different aliens, their properties, living habits and so on (in other experiments we have examined causal and definitional contents, see Byrne and Walsh, 2002). The content and instructions were adapted from Elio & Pelletier (1997) and Politzer & Carles (2001). Participants were told they would be given 'an initial set of knowledge that was true and well established at the time you began exploring. There were no mistakes at that time'. They were given a set of premises on a page of a booklet (e.g., if A then B, A) and asked to write what, if anything, followed. On the next page, they were given the contradiction (e.g., not B). They were told this information was 'additional knowledge about the planet that has come to light at a later time. This knowledge is also true and well established. The world is still the same but what has happened is that knowledge about it has increased'. Their task was 'to try to reconcile the initial knowledge and the additional knowledge. You are to write down what you now believe to be true of all the knowledge you have at this point'.

The conditionals given to one group of participants were phrased in the indicative mood, e.g., 'If the ancient ruin was inhabited by Pings, then it had a force field surrounding it', and those given to a second group were in the subjunctive mood e.g., 'If the ancient ruin had been inhabited by Pings, then it would have had a force field surrounding it'. The participants were 28 undergraduates of the psychology department at the University of Dublin, Trinity College who participated for course credit

Belief Revision Responses

The sorts of revisions that reasoners spontaneously generated fall into three main categories:

1. Revisions or negations of the conditional. Reasoners indicated that the original interpretation of the conditional needed to be revised, saying, e.g., 'A does not mean must B', 'If A don't have to B', 'not all A's do B'. Or they denied its truth, e.g., 'that B if A is false', 'the original statement that A's B is incorrect'. Revisions of the interpretation were far more common than negations.
2. Revisions or negations of the categorical. Negating the categorical for modus ponens leads to the conclusion

'not-A', for modus tollens it leads to the conclusion 'B' via the double negation 'not not-B'. In other cases, reasoners deduced a new conclusion from the contradiction and the conditional. The contradiction for modus ponens is 'not B', and with the conditional leads (via modus tollens) to 'not-B and so not-A' (which is also the denial of the categorical). The contradiction for modus tollens is 'A', and with the conditional leads (via modus ponens) to 'B' (see also Elio & Pelletier, 1997). This tactic leads to the same conclusion as the previous one, but by a different process.

3. Reasoners affirmed the contradiction and the categorical, either in combination or separately. This tactic led to the conclusion 'A and not-B' (or equivalently, 'not-B and A'). Reasoners find it difficult to make the inference from 'not (if A then B)' to the conclusion 'A and not-B' (Handley, 1996), which supports the suggestion that the conclusion 'A and not-B' is reached by a different process from the conclusions in 1.

Revisions to Factual Conditionals

We report first the results for the participants who received indicative conditionals. They made the modus ponens and tollens inferences frequently (100% and 90% respectively) perhaps unsurprisingly given the content. Most participants generated one revision (81%) and we scored those who generated more than one by their first one (see Byrne & Walsh, 2002 for details).

Table 2: The percentages of revision types for modus ponens and tollens for indicative conditionals

	Modus Ponens	Modus Tollens	Mean
Revise conditional	33	54	44
Revise categorical	41	18	30
Affirm contradiction and/or categorical	8	18	13

Participants revised their belief in the conditional somewhat more than the categorical (44% versus 30%, binomial $z = 1.32$, 1-tailed $p = .093$). However, they revised their belief in the conditional more often when modus tollens was contradicted than when modus ponens was contradicted (54% versus 33%, Wilcoxon $z = 1.94$, $p = .05$), whereas they revised their belief in the categorical more often when modus ponens was contradicted than when modus tollens was contradicted (41% versus 18%, Wilcoxon $z = 2.20$, $p = .03$), as Table 2 shows. Some of their responses consisted of affirmations of the contradiction and the categorical (A and not-B) either together or separately (13%), as Table

2 shows. The remainder of responses consisted largely of explanations of the premises or contradiction, or assertions that none of the premises were true.

The results confirm earlier findings that reasoners revise their belief in the conditional more than the categorical; perhaps more importantly the results also confirm earlier findings of an inference contradiction effect, that is, the belief revised depends on the inference contradicted. In this experiment, the direction of the inference contradiction effect is that reasoners revise the conditional more following modus tollens and the categorical more following modus ponens (for similar results see Elio, 1997; Politzer & Carles, 2001).

The generated revisions show that reasoners do not revise their beliefs solely by rejecting or disbelieving one or both of the premises, nor by doubting or expressing uncertainty in one or both of them. Instead their revisions actively attempt to re-interpret the premises in a way that genuinely reconciles the conflicting information and resolves the contradiction, for example, by calling into question the necessity of the antecedent for the consequent. This sort of revision has not been identified in previous studies which relied on presented selections only. The generated revisions also show that reasoners do not confine themselves solely to revising their categorical or conditional beliefs; a third category of responses emerged which consisted of affirmations of (one or both of) the contradiction and the categorical. It is noteworthy that no participant generated a response which simply affirmed the conditional.

Revisions to Counterfactual Conditionals

The second group of participants received counterfactual conditionals in the subjunctive mood e.g., 'If the Spracks had had high-frequency sound sensor ears then they would have had tentacles'. A counterfactual seems to mean something different from its corresponding factual conditional (Costello & McCarthy, 1999; Ginsberg, 1986; Lewis, 1973; Stalnaker, 1968). It conveys the presupposition that the facts are 'Spracks do not have high-frequency sound sensor ears' and 'Spracks do not have tentacles'. When reasoners are given a surprise memory test for counterfactuals, they mistakenly identify that they were given these facts (Fillenbaum, 1974). They judge that someone uttering a counterfactual means to imply these facts (Thompson & Byrne, in press). They make the modus tollens inference more readily from a counterfactual than from a corresponding factual conditional (Byrne & Tasso, 1999). They make the modus ponens inference just as readily from both sorts of conditional.

Since counterfactual conditionals convey both the facts 'Spracks do not have high-frequency sound sensor

ears', 'Spracks do not have tentacles', as well as the suppositions, 'Spracks have high-frequency sound sensor ears', 'Spracks have tentacles', we considered that reasoners would not revise their beliefs in counterfactual conditionals as often as factual conditionals.

Table 3: The percentages of revision types for modus ponens and tollens for counterfactual conditionals

	Modus Ponens	Modus Tollens	Mean
Revise conditional	16	38	27
Revise categorical	53	13	33
Affirm contradiction / categorical	18	29	24

The results support our conjecture, as Table 3 shows. Once again, participants made the modus ponens and tollens inferences frequently (96% and 87% respectively). A comparison of the means in both tables shows that reasoners revise a factual conditional more than a counterfactual conditional (44% vs 27%, $\chi^2 = 5.29$, $p < .05$). For a counterfactual conditional, they often affirmed the contradiction and the categorical (together or separately). The results also show the presence of an inference contradiction effect, and its direction is the same for counterfactual as for factual conditionals.

Cognitive Processes in Belief Revision

Different cognitive processes may be required to alter conditional and categorical beliefs following modus ponens and tollens inferences from a factual conditional. The different effects of the counterexample, A and not-B, on the way reasoners revise their beliefs may arise because of the mental representations they have constructed in the course of making an inference.

Reasoners may understand conditionals by keeping in mind different possibilities (Johnson-Laird & Byrne, 1991). The explicit set of models for the conditional 'if A then B' are as follows:

A B
Not-A not-B
Not-A B

where in the diagram 'not' is a propositional-like tag to indicate negation. Reasoners who interpret the conditional as a biconditional will construct the first two models in the set only. Regardless of their interpretation, reasoners may construct an initial set of models that makes some information explicit, but leaves other information implicit, because of the constraints of working memory:

A B

...

where the three dots represent an implicit model (Johnson-Laird & Byrne, in press).

Reasoners can make the modus ponens inference from this initial set of models. The categorical, A, is consistent with the explicit model:

A B

which supports the parsimonious conclusion, B. To make the modus tollens inference, they must flesh out the initial set of models to be more explicit. The information, not-B, cannot be incorporated readily into the initial set of models. However, it can be incorporated into the fleshed-out models, it eliminates two of them and it leaves a single model:

not-A not-B

which supports the parsimonious conclusion, not-A.

The process by which the two inferences are made differs. The modus ponens inference is made from the initial set of models, but the modus tollens inference is made only after fleshing out the models to be explicit, eliminating models that are inconsistent. This difference in the process of making the inferences may affect the revision of beliefs.

Consider the contradiction to the modus ponens inference. Reasoners must incorporate the contradiction 'not-B'. They made the inference, 'B', based on the initial set of models, and so they have the option of returning to the initial set to flesh them out to be more explicit. Faced with the contradiction, they may decide they need to think more fully about the possibilities compatible with the conditional. People often return to earlier possibilities to think about what might have been (e.g., Byrne & McEleney, 2000). When they do so they can incorporate the contradiction 'not-B' into one of the fleshed out models:

Not-A not-B

The new model indicates that the belief to revise is the categorical, A.

For the modus tollens inference, reasoners must incorporate the contradiction, A. They made the modus tollens inference by fleshing out the models to be more explicit and eliminating all but the model:

Not-A not-B

They do not have the option of returning to flesh out the initial models again, since they have executed that option in the process of making the inference. In the course of making the inference they have considered several alternatives and eliminated them, 'cashing out' the possibilities to one single remaining possibility. The contradiction 'A' cannot be incorporated into the existing model and so the belief to revise is the conditional, if A then B.

The essential revision principle may be that a contradiction can be incorporated into one of the possibilities compatible with the conditional, if these

possibilities have not been thought about and eliminated already. In the case of modus ponens, the only possibility compatible with the contradiction and the conditional (not-A not-B) is incompatible with the categorical (A) and so the categorical must be revised. In the case of modus tollens, the possibilities have been exhausted already in the course of making the inference, and so the conditional itself must be revised. The inference contradiction effect, that the belief revised depends on the inference made before the contradiction, may arise because different inferences require people to keep in mind different possibilities, which subsequently limits their room for maneuver in incorporating contradictory information.

Reasoners can rely on background knowledge to add or eliminate possibilities (Johnson-Laird & Byrne, in press). As a result, when they have relied on knowledge to add or eliminate possibilities, their revisions may *not* be influenced by the inferences they have made (Byrne and Walsh, 2002). For example, given a causal conditional, 'if water was thrown on the campfire then it went out', and 'the fire did not go out', reasoners make the modus tollens inference, 'water was not thrown on the campfire'. But when the inference is contradicted 'water was thrown on the campfire' they can incorporate it by saying, for example, 'not enough water was thrown on the campfire'. Reasoners may even short-cut the process by 'matching' various models (Legrenzi, Girotto, & Johnson-Laird, 2002). The inference contradiction effect may be a feature of certain kinds of content.

Modifying or Abandoning Beliefs?

Previous studies have focused on what beliefs people disbelieve, deny or reject, doubt or are uncertain about. However, a contradiction can call for a revision to the original *interpretation* of the premises. A putative counterexample, A and not-B, does not necessarily mean that a conditional, if A then B, is false. Our participants generated revisions to the interpretation (e.g., 'A's do not necessarily have B's', 'Some other variable affected B, e.g., C') more often than they indicated disbelief, denial, rejection, doubt or uncertainty about the conditional's truth.

Reasoners may reach many different interpretations of a conditional (Johnson-Laird & Byrne, in press). One interpretation of 'if A then B' is that A is sufficient but not necessary for B, and a second is that A is both necessary and sufficient for B. These 'conditional' and 'biconditional' interpretations are inconsistent with the counterexample, A and not-B. But other interpretations are consistent with it, for example, that A is necessary but not sufficient for B. This 'reverse conditional' interpretation may be common in everyday reasoning (Byrne, Espino, & Santamaria, 1999).

The reverse conditional interpretation can occur when an additional requirement is made explicit, e.g., 'if the ruin was inhabited by Pings then it had a force field, if they had to protect their habitations then it had a force field'. The modus ponens inference from, e.g., 'the ruin was inhabited by Pings' is suppressed (Byrne, 1989). Reasoners say there is not enough information, or they incorporate the second requirement e.g., 'The ruin had a force field if the Pings had to protect their habitations' (Byrne, et al, 1999). They select options that refer to the second requirement (e.g. Diuessaert, Schaecken, Schroyens, & d'Ydewalle, 2000) and they judge the requirements to be conjoint (Byrne & Johnson-Laird, 1992). When both requirements are affirmed they readily make the inferences (Byrne, 1989; 1991), and they can be enhanced when reasoners know the additional requirements have been satisfied (Manktelow & Fairley, 2000). The suppression is increased when the additional requirement is emphasized, by phrasing it as a biconditional, 'if and only if the Pings had to protect their habitations...' (Byrne, et al, 1999), by relying on familiar content (Chan & Chua, 1994; see also Bonnefon & Hilton, in press), by qualifying its satisfaction (Stevenson & Over, 1995), or by specifying that the requirement was uttered by an expert rather than a novice (Stevenson & Over, 2001). Conditionals with many additional requirements lead to more suppression (Cummins, Lubart, Alksnis, & Rist, 1991; see also Elio, 1997). The conditions in which a reverse conditional are true can be specified with as much certainty as the truth conditions of a conditional or biconditional (but see Politzer & Braine, 1991; Stevenson & Over, 1995; 2001).

Our results show that revising belief in a conditional can mean modifying the original interpretation, for example changing from a conditional interpretation to a reverse conditional one, rather than abandoning belief in the truth of the conditional. In everyday life, just as in scientific thought, it may be rare to abandon entirely either a theory or a fact, upon discovery of another contradictory fact; instead reasoners may progress by attempting to modify their interpretation to restore consistency.

Conclusions

In everyday reasoning, the conclusions to inferences can be readily withdrawn in the light of subsequent information, that is, they are non-monotonic. An important task in everyday inference is the revision of beliefs in the light of contradictions. The results also show an inference contradiction effect, that is, reasoners revise a categorical belief when a modus ponens inference is contradicted and they revise a conditional belief when a modus tollens inference is contradicted. Our results show that reasoners revise their belief in a factual conditional more than a counterfactual

conditional. Our novel revision generation task allowed us to capture some of the rich re-interpretations that people produce to resolve contradictions through modifying rather than abandoning beliefs.

Acknowledgements

We thank Jean-Francois Bonnefon, Renee Elio, Uri Hasson, Phil Johnson-Laird, Mark Keane, and Guy Politzer for helpful comments on an earlier draft and Michelle Cowley and Michelle Flood for help with the experiment. Abstract

Research on anthropomorphic agent interfaces has produced widely divergent results. We suggest that this is due to insufficient consideration of key factors that influence the perception and effectiveness of agent-based interfaces. We propose a framework for studying anthropomorphic agents that can systematize the research. The framework emphasizes features of the agent, the user, and the task the user is performing. Our initial experiment within this framework manipulated the agent's appearance (lifelike versus iconic) and the nature of the user's task (carrying out procedures versus providing opinions). We found that the perception of the agent was strongly influenced by the task while features of the agent that we manipulated had little effect.

Introduction

If you could ask for assistance from a smart, spoken natural language help system, would that be an improvement over an on-line reference manual? Presumably the answer, in most cases, is yes, for two reasons. First, the spoken natural language aspect would allow you to speak your questions rather than having to type them. Generally this is a faster approach for most people. Second, the smart aspect would improve the chance of the help system finding the information you want even if you do not state the query using the correct or most appropriate terms.

The state of the art in this style of interface is a human user consultant. Does it matter that the user consultant has a face and that the face can have expressions and convey a personality? Would a face affect you in terms of your comfort and satisfaction with the interaction? Would the presence of a face make the help or advice you receive more persuasive? The answers to such questions have implications for the design of training systems, customer service, information kiosks, and many other applications.

Many people believe that anthropomorphic computer interfaces have great potential to be beneficial for a number of reasons. Agents could act as smart assistants, much like travel agents or investment advisors, helping people manage the ever-growing amount of information encountered today (Lyman & Varian, 2002). Further, a conversational interface appears to be a natural dialog style in which the user does not have to learn complex command structure and functionality (Laurel, 1990).

An anthropomorphic interface could use intonation, gaze patterns, and facial expressions, in addition to words, for conveying information and affect. The human face seems to occupy a privileged position for conveying a great deal of information, including relatively subtle information, efficiently (Fridlund & Gilbert, 1985). Anthropomorphic interfaces could make a computer more human-like, engaging, entertaining, approachable, and understandable to the user, thus harboring potential to build trust and establish relationships with users, and make them feel more comfortable with computers.

These potential advantages are balanced by strong negatives. Anthropomorphic agent interfaces are viewed by some researchers as being impractical and inappropriate. Current speech recognition, natural language understanding, and learning capabilities of computers still fall far short of any human assistant.

More specifically, it has been proposed that agent systems disempower users by clouding issues such as who is responsible for a system's actions (Lanier, 1995). Others feel that user interfaces are more beneficial when they clearly reflect the commands available to a user and present the objects that a user can act upon (Shneiderman, 1997). Furthermore, critics argue that agent interfaces may mislead both users and designers, increase user anxiety, reduce user control, undermine user responsibility, and destroy a user's sense of accomplishment (Shneiderman & Maes, 1997). Many current anthropomorphic or personified interfaces are viewed as being annoying, silly characters who hinder rather than enhance productivity (e.g., the Microsoft Paper Clip).

Although strong opinions have been voiced on both sides of this issue, relatively little careful empirical research on anthropomorphic interfaces has been conducted, and the results from this research have been contradictory or equivocal (Cassell, 2000).

Our goal is to develop a framework to systematically evaluate and understand the autonomous agent as a user interface paradigm. The present paper outlines the framework and an initial study that examines two issues within this framework. The first is whether the degree to which an interface agent is anthropomorphic has a measurable effect on users. Note that anthropomorphism is not a dichotomy but rather a continuum. One can think of interfaces with full fidelity video or 3D images of people to

more caricature-style characters to 2D cartoons of people or personified characters such as dogs or toasters.

The second issue is to what extent the nature of the task will influence a user's perception of an agent. Some tasks might be more likely to induce a user to imbue the agent with human-like qualities (such as if the user had to engage the agent in a debate) while other tasks might lead the user to view the agent simply as a reference tool (e.g., for providing reminders of keystrokes for a software application) with no "individuality."

Related Work

A few studies have revealed that anthropomorphic agents are attention-grabbing and people make natural assumptions about the intelligence and abilities of those agents. King and Ohya (1996) found that a dynamic 3D human form whose eyes blinked was rated more intelligent than any other form, including non-blinking 3D forms, caricatures, and geometric shapes.

One common trend discovered in studies is that anthropomorphic interfaces appear to command people's attention, both in positive and negative senses. Takeuchi and Nagao (1995) created conversational style interaction systems that allowed corresponding facial displays to be included or omitted. According to their metrics, the conversations with a face present were more "successful." Across two experiments they found that the presence of a face provided important extra conversational cues, but that this also required more effort from the human interacting with the system and sometimes served as a distraction.

Other studies have shown that the attention garnered by an anthropomorphic interface had a more positive effect. Walker, Sproull, and Subramani (1994) found that people who interacted with a talking face spent more time on an on-line questionnaire, made fewer mistakes, and wrote more comments than those who answered a text questionnaire. Koda (1996) created a Web-based poker game in which a human user could compete with other personified computer characters including a realistic image, cartoon male and female characters, a smiley face, no face, and a dog. She gathered data on people's subjective impressions of the characters and found that people's impressions of a character were different in a task context than in isolation and were strongly influenced by perceived agent competence.

An influential body of related work is that of Nass and his colleagues. Their efforts focus on the study of "Computers as Social Actors." They have conducted a number of experiments that examined how people react to computer systems and applications that have certain personified characteristics (Nass, Isbister, & Lee, 2000; Nass, Steuer, & Tauber, 1994; Rickenberg & Reeves, 2000). Their chief finding is that people interact with and characterize computer systems in a social manner, much as they do with other people. Furthermore, they suggest that findings in the social psychology literature (e.g., individuals with similar personalities tend to get along

better than do those with different personalities) apply even when one of the two participants is a machine.

The studies cited above, and others, suggest that people are inclined to attribute human-like characteristics to agents and that a variety of factors might influence how positively the agents are viewed. Dehn and van Mulken (2000) provide a more extensive review of this literature.

A Framework for Research on Anthropomorphic Interface Agents

To effectively and systematically investigate the use of anthropomorphic interface agents, one needs to consider the key factors that will affect the usefulness of such interfaces. We propose an investigative framework composed of three key components: characteristics of the user, attributes of the agent, and the task being performed.

We believe that serious empirical study in this area must systematically address each of these factors and understand how it affects human users. Below, we provide examples of individual variables within each factor that could potentially influence user performance and impressions.

Factor 1: Features of the User

Potential users vary, of course, in many ways. However, there are certain features that may be quite likely to affect how useful a user finds an agent. These features include:

Personality: Researchers have identified what are referred to as the "Big Five" traits that seem to be quite useful in describing human personalities: extraversion, openness, agreeableness, neuroticism, and conscientiousness (e.g., McCrae & Costa, 1987). While any such breakdown is debatable, it seems reasonable to examine whether users' positions on these, or other, trait dimensions predicts how they will respond to agents.

Background Knowledge: A user who has a good deal of background knowledge in a domain might prefer an agent that is reactive and that the user can call upon when he or she needs some low-level bit of information or has a low-level task that needs to be done. Conversely, a user who is learning how to carry out tasks in a particular domain might welcome strategy advice from an agent, particularly if the agent can analyze the strategy and provide reasons for why the strategy might be altered.

Other Variables: Other user-related variables include gender, age, and computer experience.

Factor 2: Features of the Agent

Fidelity: Earlier studies suggest that more realistic-appearing, 3D human representations are perceived as being more intelligent, which could be viewed positively or negatively. However, realistic-appearing agents are more difficult to implement, so if user performance is improved by the presence of an agent, but does not vary according to appearance, simpler caricature style characters would be advantageous.

Presence: Is an agent's face always present on the screen or does the agent only appear when it is engaged in a dialog

with the user? One might hypothesize that an ever-present agent would make users uneasy by producing an effect of being watched or evaluated all the time.

Role: Should an agent act as a partner in the task or should it contribute only in clearly specified ways? For instance, an agent might be able to offer strategy guidance for design tasks. Alternatively, it might provide only lower-level procedural "how to" information.

Initiative: Should an agent proactively make suggestions and offer guidance or should it respond only when directly addressed? A proactive agent might be viewed as being "pushy" and might bother users, or it could be viewed as being extremely helpful and intelligent if it acts in situations in which the user is unsure of how to proceed or is so confused that he or she is unable to form a coherent help request.

Other Variables: Other agent-related variables to consider are expressiveness, speech quality, "gender," "personality," and competence.

Factor 3: Features of the Task

Tasks can vary in a variety of ways. Some tasks can be opinion-like (e.g., choosing what to bring on a trip) while others are more objective (e.g., solving a puzzle) in terms of assessing the quality of a solution. Some involve a good deal of high-level planning (e.g., writing a talk) while others are more rote (e.g., changing boldface words into italics). Tasks might be classified along some or all of the dimensions listed below:

Objectiveness: The situation might be an opinion-based one in which the user is seeking advice and recommendations on some topic (e.g., which items to pack for a trip to Europe). Alternatively, the user might be carrying out an objective task such as acquiring facts (e.g., finding the keystroke combination for a particular command in a software application).

Intent: The user could have a learning goal or alternatively may be carrying out a set of steps in a familiar domain. In the latter, the user might want help with low-level details whereas in the former the user is looking for guidance as to the structure of the domain.

Other Variables: Other task-related variables to consider are domain, degree of time pressure, duration, and consequences of the quality of task performance.

The number of variables within each factor is certainly larger than the number we have identified here. No doubt these factors will also interact. For instance, a novice attempting to carry out a task in a particular domain might welcome proactive comments/advice from an agent while someone with more experience could get annoyed.

With respect to measuring the usefulness of an agent, we have to consider which dependent measures are most appropriate. Towards the more objective end, a user's performance on a task in terms of accuracy and time--when such measures are meaningful--can give one indication of usefulness. Thus, time and errors would be appropriate measures for a text-editing task. Towards the more

subjective end, a user is likely to have a number of affective reactions to an agent. These reactions might manifest themselves in terms of how much users liked the agent, how intrusive they found the agent, how they perceived the agent's personality, and how willing they are to use the agent in the future. We can certainly assess a user's liking and satisfaction towards an agent, but if the user can carry out the tasks more effectively with the agent regardless of liking and satisfaction, then how important are those variables? On the other hand, long-term use of an agent might be predicted by liking and satisfaction.

The likelihood of a user following an agent's advice might be another interesting measure of the usefulness of an agent. While advice-following would certainly be at least partly a function of the quality of the advice, it will also be impacted by how the user feels about the agent (how many children ignore the advice of their parents merely because it is the parents giving the advice?).

Experiment

Overview

One fundamental issue in the quality of agent interfaces is competence (Maes, 1994). It appears obvious that perceptions of anthropomorphic agent interfaces will be strongly influenced by the competence of the supporting software system and the quality of the replies and suggestions made by the agent. We chose to factor out competence as an influence. If our experiments uncover that people's performance is not enhanced and they dislike anthropomorphic user interfaces even though the system is competent, then that is an important and strong result that other researchers and developers need to understand. To remove competence as a factor, we employed a "Wizard of Oz" (Dahlback, Jonsson, & Ahrenberg, 1993) methodology (described below).

The experiment manipulated the agent fidelity and the task objectiveness variables because prior work and our framework suggest they seemed likely candidates to have an affect on the perception of agents. Usefulness was evaluated via both the performance and satisfaction dimensions. We hypothesized that user reactions to the agent would vary as a function of the objectiveness of task. A task that required the user to debate the merits of his or her opinion (about items to pack on a trip) might lead the user to feel the agent had more of a personality (for good or for bad) compared to a task in which the user made use of the agent more as a reference tool (i.e., reminding the user of keystroke commands for a text editor). We also hypothesized that users might find the agent to be more useful in its role as a reference source rather than as an entity that provides opinions. Finally, we expected that the more life-like the agent appeared, the more likely the user might be to ascribe qualities such as personality and intelligence to the agent, but objective performance would likely not be affected by appearance.

Participants

Thirty-nine undergraduates participated for course credit and were randomly assigned to conditions. Participants had a variety of majors and computer backgrounds.

Procedure and Design

Participants were run individually using a computer equipped with a microphone and speaker. Participants performed two tasks: a travel task and an editing task. The travel task was chosen to be a type of creative, opinion-based task in which interacting with an agent might be viewed as an opportunity to think more deeply about the task by discussing points of view about the importance of travel items. The editing task was chosen to represent an opportunity to use an agent primarily as a reference source rather than as a guide or teacher.

The travel task involved a hypothetical situation in which the participant had a friend who was flying overseas on his first international trip. The task was to recommend six items for the person to take with him from a pool of 12 items and to rank the six items in order of importance.

After the participant did the initial ranking using a simple software interface, a computer agent who supposedly had knowledge about international trips appeared. The agent made a predefined set of suggestions in which it recommended changing the rankings of four of the six choices and it agreed with the ranking of two other items. For example, the agent first suggested promoting the person's fourth item to the first position, demoting the first item but keeping it in the top six. The agent explained the reasoning for its suggestion at every stage and asked the participant what he or she thought about the suggestion. After the participant responded to the agent's comment on a particular item, the agent would say one of several conversational conventions (e.g., "OK, let's continue") so that it could move on to the next suggestion. After the agent finished providing feedback on the rankings, the original rankings were displayed on the screen and the participant was given the opportunity to change the rankings. After doing the re-ranking, participants filled out a questionnaire about the agent and were asked a few questions about the agent and related issues by the experimenter.

The editing task required participants to use an unfamiliar text editor to modify an existing document by making a set of prescribed changes to the document. Participants first viewed a short video that described the various functions (e.g., copy, paste) and the specific key combinations needed to issue the commands. Participants were then shown a marked-up document that required a set of changes such as deletions, insertions, and moves, and they were instructed that if at any time they could not remember the keystrokes for a particular function, they could ask the agent for help. Pilot testing was conducted to ensure that the number of commands was sufficiently large so that participants would be likely to need to ask the agent for help. After completing the editing tasks, participants

again filled out a questionnaire about the agent and answered questions from the experimenter.

The agent was controlled through a Wizard of Oz technique. One experimenter was in the room with the participant to introduce the experimental materials, and a second experimenter was in an adjacent room, monitoring the questions and responses made by the participant. The second experimenter insured that the agent responded in a consistent manner using a prepared set of replies.

Two between-subjects variables were manipulated: type of agent (animated, stiff, iconic) and task order (travel task then editing task or vice versa). The left side of Figure 1 shows the face of the agent in the animated and stiff conditions. The animated agent (donated by Haptik Corp.) was 3D, with a female appearance--though somewhat androgynous--that blinked, moved its head, and produced certain facial expressions in addition to moving its mouth in synchronization with the synthesized voice. The stiff agent had the same face as the animated agent but moved only its mouth. The iconic agent (see the right side of Figure 1) was a light-bulb icon that had arrows appear whenever it spoke.

One design issue about this experiment should be flagged. Although our key task manipulation was the "objectiveness" of the task (i.e., the travel task being less objective and the editing task being more objective), the nature of the agent also was varied as a function of the task. The agent was completely reactive in the editing task; it provided information only when requested. However, in the travel task the agent provided feedback regardless of the participants' desire. A cleaner version of the experiment would have been to hold the "nature" of the agent constant across the tasks. We allowed this confounding to occur here because we were interested in getting participants' reactions to certain human-like attributes of the agent but did not have the resources to run the additional conditions that would have been required to completely cross this factor with the task and appearance manipulations. In future work we plan to systematically investigate this reactive/proactive dimension.

Figure 1: Appearance of Agent in Animated and Stiff Conditions (left) and Iconic Condition (right).

Measures

Both objective and subjective measures were used. One objective measure was, for the travel task, whether

participants changed their rankings as a function of the agent's feedback. For the editing task we measured how long it took participants to complete the edits. The primary subjective variables were the responses to the individual items in the questionnaires and the answers to the questions posed by the experimenter. The questionnaire items used a five-point Likert scale (1 = strongly agree, 5 = strongly disagree) that addressed a number of qualities of the agent (see Table 2). The questions posed by the experimenter were open-ended and provided participants an opportunity to give their impressions about the agent's personality, helpfulness, and intelligence.

Results

In the data analyses we found that the task order manipulation did not have an effect, so in the interest of simplicity we will collapse across that factor in the presentation and discussion of the results.

Performance Measures. With respect to more objective measures, Table 1 shows that participants were more likely to change the rankings of items that the agent disagreed with compared to items that the agent agreed with, $F(1, 36) = 38.48$, $MSE = .07$, $p < .0001$. There was no effect of type of agent, $F(2, 36) = 0.9$, $MSE = .11$, $p = .42$. There was no interaction, $F(2, 36) = 1.25$, $p = .30$.

Table 1: Proportion of Travel Items with Changed Rankings as a Function of Type of Agent & Agent Advice.

	Animated (<i>n</i> = 14)	Stiff (<i>n</i> = 12)	Iconic (<i>n</i> = 13)
Suggested Change	.82	.90	.77
Keep Rank	.57	.42	.38

The time (in seconds) to do the editing task did not differ as a function of agent (animated: 714.8, stiff: 568.7, iconic: 671.1); $F(2, 31) = 1.78$, $MSE = 37637.22$, $p = .19$ (5 participants did not do the editing task).

Questionnaire Responses. Table 2 shows the mean responses to the questionnaire items for the different agent conditions after the travel and editing tasks (there were 5 participants who did not do both tasks and they are excluded from Table 2). There was no effect of agent type for any of the questions. For two of the items, worthwhile and intrusive, there was an effect of task (worthwhile: $F(1, 31) = 15.68$, $MSE = .45$, $p = .0004$; intrusive: $F(1, 31) = 20.28$, $MSE = .23$, $p = .0001$). The agent was rated more worthwhile and less intrusive after the editing task compared to the travel task. These results make sense. First, the editing task required most participants to rely heavily on the agent to remind them of commands, thus making the agent seem worthwhile. Second, the uninvited critique of participants' rankings of travel items could certainly have seemed intrusive.

While group differences did not exist on most of the questionnaire items, it is interesting that for most items, the average response tended to be in the positive direction. Participants felt positively, on average, about the agent.

Interview Responses. While participants made a

number of interesting and insightful comments about the agent in response to questions from the experimenter, a simple tally of responses shows reactions to the agent that again varied as a function of task. Virtually all participants found the agent helpful for both tasks. Participants were much less likely to consider the agent to have a personality after doing the editing task compared to the travel task. This makes sense because the agent was merely providing subjects with information on commands in the editing task. In the travel task the agent expressed its "opinions."

Finally, it is worth noting that in general the agent was perceived as more intelligent after the travel task than after the editing task. At one level this seems odd because the agent had all the answers for the editing task. However, as demonstrated by some participants' comments, the agent was perceived as very limited in the editing task; it knew about editing commands and probably little else (despite the fact that it also appeared to understand spoken language!). In the travel task though it presumably gave the impression of having sufficiently deep knowledge about travel such that it could give feedback on the importance of various items one might take on a trip. While some of the participants' responses to the agent indicated that they disagreed with its suggestions, they appeared to believe that the suggestions were at least thoughtful.

Discussion

In addition to the results reported above, we learned a great deal by observing participants' behaviors and responses in the sessions. One key question we had was how would the participants interact with the agent in the two different tasks. In the editing task, participants seemed very comfortable asking the agent for assistance. Participants requested help an average of 6.5 times. However, in the travel task participants seemed reluctant to engage the agent in a dialog. Only a few replied with more than a few words when the agent engaged them. There was clearly awkwardness to the interaction.

The agent's social abilities and personality (or lack thereof) were noted by a number of the participants. In the travel task, we intentionally had the agent begin the session saying, "Hello, [person's name]." Three participants explicitly mentioned this feature, one stating, when asked if the agent had a personality, "Yes, respectful. It said, '[my name]', and 'I agree with this.'...I thought that was very funny. That was really cool."

Other comments implying a personality included, "Seemed a lot like a travel agent that was in a hurry," and "helpful, but kind of annoying," and "he seemed almost irritated when I didn't agree with him." One participant who did the editing task first, stated after the task that the agent did not have a personality, "It was just directed at answering questions. It had no inflections." But when asked again after the travel task, the participant responded, "It was still mechanical, but you could feel the attempt at being more personable. It acknowledged my responses, asking me to elaborate. The responses were at a more

personal level." Participants' willingness to ascribe a personality to the agent based on a few comments by the agent in one task suggests that people might be predisposed to "finding" a personality in an agent. If the effects of seeing a personality in an agent can be better understood, such a predisposition might be exploited for good purpose by designers.

Conclusion

Anthropomorphic interface agents might be one of the best interface approaches ever devised. Or they might not. Equivocal results from prior research make it virtually impossible to decide this matter. The difficulty with prior

work has been its lack of systematicity in examining key factors and the use of dependent measures that often did not appropriately assess subjective experience and objective performance.

In this paper we introduced a framework for systematically examining the effects of anthropomorphic agents on user performance and subjective responses. We performed an initial experiment within this framework that suggested that type of task may play an outsized role in the perception of agents. We plan to use our framework to guide additional studies and hope other researchers find it useful and that it will allow future experiments to build on each other more effectively than in the past.

Table 2: Responses to Questionnaire Items as a Function of Type of Agent and Task.

	Animated (n=12)		Stiff (n=12)		Iconic (n=10)		AVG
Agent was	Travel	Edit	Travel	Edit	Travel	Edit	Travel/Edit
Worthwhile	2.50	1.58	2.25	1.42	2.30	2.10	2.35/1.57
Intrusive	2.83	3.50	3.50	4.00	3.40	3.80	3.24/3.76
Friendly	2.67	2.67	2.42	2.50	2.40	2.80	2.50/2.65
Annoying	3.25	3.33	2.83	3.25	3.20	3.80	3.09/3.44
Intelligent	2.58	2.92	2.58	2.50	2.40	2.70	2.53/2.71
Cold	3.25	3.08	3.00	2.67	3.70	3.30	3.29/3.00
Agent has clear voice	2.33	2.58	2.58	2.33	2.50	2.40	2.47/2.44
Enjoyed interacting with Agent	3.08	3.17	2.75	2.83	2.70	2.90	2.85/2.97
Agent helped with task	2.25	1.50	1.67	1.50	2.00	2.30	1.97/1.74
Like to have agent	2.83	2.67	2.58	2.33	2.20	2.40	2.56/2.47

Note: Responses were on a scale from 1 (strongly agree) to 5 (strongly disagree).

Abstract

Given practice, people generate new more efficient strategies for achieving desired goals. However, some researchers have observed that even experienced users of computer systems persist with relatively inefficient strategies. One reason for these findings may be a reduced opportunity to use efficient strategies in tasks where higher goal constraints are present. In this study half of the participants completed a drawing task in Microsoft PowerPoint in which they had to design the layout of a computer room and study area; the other half completed an equivalent drawing task that involved no higher goal constraints. Those with higher goal constraints were slower to generate more efficient strategies. This can be accounted for by a reduced opportunity to use 'efficient' strategies. Experience in other computer packages and strategic knowledge also influenced strategy generation.

Introduction

When people learn a new skill they often move through a series of progressively more efficient strategies. Practicing a task does not only result in faster performance, but also leads to the generation of new strategies (Delaney, Reder, Staszewski and Ritter, 1998; Charman and Howes, 2001). For example, Charman and Howes (2001) found that people can successfully generate more efficient drawing strategies when using Microsoft PowerPoint as a result of practice on component procedures.

However, Carroll and Rosson (1987) observed that the skills of computer users "tend to asymptote at relative mediocrity" (p.1). Similarly, Bhavnani and John (1997) reported that even after a number of years of experience and formal training in a computer aided design package, many users had not adopted more efficient strategies. The reason, they suggest, was not related to the standard of interface design or experience with the package, but to an absence of strategic knowledge. Bhavnani, John and Flemming (1999) found that people stay with inefficient methods unless they are taught efficient strategies explicitly.

One explanation for the conflicting observations of Charman and Howes (2001) and Bhavnani and John (1997) is that participants had different primary goals. Whereas the task used by Charman and Howes (2001)

involved participants reproducing simple pictures in Microsoft PowerPoint, Bhavnani and John (1997) observed CAD users completing real work tasks, which would have imposed higher goal constraints. It is possible that the presence of higher goal constraints inhibits the generation of more efficient strategies and/or reduces the opportunity to use them. Higher goal constraints when preparing a report or presentation, for example, might concern syntax and semantics, and when designing a building they might concern functionality and aesthetic quality.

Higher goal constraints may hinder strategy generation by changing the user's focus. This is consistent with the observations of Carroll and Rosson (1987). They found that people were unwilling to take time out to read a manual because they were 'end-product' focused, i.e. their paramount concern was with completing the tasks at hand. It is possible that Bhavnani and John's (1997) participants failed to generate more efficient strategies because they were focused on meeting higher goal task constraints derived from the work domain. The focus in Charman and Howes' (2001) study however was on the method for which more efficient strategies were available.

In addition, the presence of higher goal constraints may reduce the opportunity to use efficient strategies. When taking into consideration higher goal constraints, sub-goals tend to be smaller, and so strategies that exploit the iterative power of the computer package are not as beneficial. When working with higher goal constraints computer users may generate strategies that are efficient given the sub-goal structure of the task, but which appear inefficient when viewed from the perspective of the end product. E.g. It is possible to imagine an efficient way of drawing a *given* floor plan, but when a person is *designing* a plan they do so interactively, using the device as repository for partial solutions.

While, substantial efforts have been made to model strategy change (e.g. Shrager and Siegler, 1998), these models do not address the issue of *when* people deploy strategy generation mechanisms. These models instead have addressed details of the mechanisms by which new strategies are generated from existing strategies. For example, Crowley, Shrager and Siegler (1997)

proposed that people use both a metacognitive and an associative mechanism. The metacognitive mechanism is of particular interest here because it requires deliberate and resource intensive problem solving. Our interest in this paper is in the extent to which higher goal constraints moderate ability or opportunity to beneficially deploy metacognitive problem solving.

We predict that there will be a negative impact of higher goal constraints on the generation of efficient strategies. In the following experiment, whether or not participants had a higher level goal to meet was manipulated. The higher-goal task was to design the layout of a computer room and study space. In the no-higher-goal task participants copied and pasted an equivalent number of computers and desks into a large blank area. To complete the tasks a range of strategies varying in efficiency, with the same component procedures, could be used. Participants could copy and paste just one item (a computer or a desk) at a time, or could copy and paste multiple items at once. Previous experience and strategic knowledge were also examined as factors affecting strategy generation.

Method

Participants

Twenty-four undergraduates who were regular computer users, ranging in age from 18 to 26, took part in the experiment for 1½ hours of course credit or for payment of £6. All participants were given the same amount of credit or payment to take part in the study, no matter how long they took, in order to encourage efficient completion of the tasks.

Design

The study involved three between-subjects factors. The first was task type. In one condition participants were given a higher goal, where they were asked to design the layout of a computer classroom and a study area (see Appendix I). This higher goal gave rise to several design constraints that determined the manner in which the desks and computers could be arranged. The goal for these participants was to take into consideration the constraints outlined and also to consider the best use of space. In another condition participants did not have a higher goal in mind, they were asked to copy and paste an equivalent number of computers and study desks into a large blank space. A median split (over both task type conditions) on two pre-test measures, experience and strategic knowledge, created two more between subjects factors.

Procedure and Materials

The participants completed an informed consent form and then a short online spatial IQ test (Crampton and

Jerabek, 2000), which consisted of ten questions, giving a score out of 100. Participants were then asked to complete a short questionnaire that asked about prior experience with Microsoft PowerPoint, as well as other software packages with drawing functions and Microsoft Word. The tuition phase was then completed, which ensured that the participants mastered basic drawing skills (drawing, moving, altering, fencing to select, copying and pasting a single shape). The participants were informed that they should only use functions identified in the tutorial stage. These included fencing, copying and pasting, but, for example, excluded duplication and grouping.

After the tuition phase the participants completed an open-ended questionnaire designed to assess knowledge about the device. Ten questions relevant to the key concepts particular to working with more than one item at a time were included. Five questions related to fencing multiple shapes with space between them and five related to the manipulation of multiple shapes.

The participants then completed a pre-test stage where they were asked to draw eight 2-shape items in as few moves as possible (Figure 1). The strategy used by the participant was coded and scored (1-7) according to the relative efficiency of the strategy based upon the coding framework outlined in Charman and Howes (2001). For example, participants were given a score of 1 if they drew each shape one by one, and a score of 7 if an exponential copying strategy was used (exponentially increase the number of items made each time copy and paste are used). This score was taken as a measure of strategic knowledge.

Figure 1: Pre-test task.

The main task of the experiment was then conducted. Participants were informed that there was an online help facility that they could choose to consult if they wished (this was available freely to the participants and could be accessed by selecting an open Internet Explorer window). For the main task, the no-higher-goal condition participants were given a key with sample desks and computers in it, and asked to reproduce 54 study desks and 148 computers in the space provided. The participants were all instructed that they could fence (to select), copy and paste the computers and study desks provided in the key.

In the higher-goal condition, participants were asked to plan the layout of a new extension to the Psychology building (Appendix I). In the proposed extension there was a study area where study booths were to be placed, and a computer classroom where computers were to be

placed. Participants were given design constraints for which visual measures were provided, such as making sure that there were gangways, access to desks and space between computers. Although participants were told that a design could include 148 computers and 54 desks, the task was over when the participant felt they had finished their design, with the constraints met.

Participants were instructed to complete the task in as few moves as possible. Finally participants filled in another device representation questionnaire. Microsoft PowerPoint 97 was used to carry out the drawing tasks.

Strategies

To complete the task, several strategies could be employed. It was possible to work with an individual shape, as the composite parts of each item (a computer or desk) were not grouped together. A better way to complete the task was to draw a fence around one item and then copy, paste and move the item. An even better strategy was to work with more than one item at a time. In order to do this a participant needed to know that multiple items with space between them could be selected at once (by drawing a fence around them, see Figure 2) and then manipulated (copied, pasted and moved) simultaneously. Finally, the exponential copying strategy allowed very fast completion of the task. Here the number of copies produced at once increases exponentially.

Figure 2: Fencing, by using the mouse to click and drag from the start point and releasing at the end point.

Results

Each move made by a participant was recorded, allowing a fine-grained analysis of performance. An individual move was taken to be either a key-stroke (e.g. delete) or a purposeful mouse-click (e.g. copy or select shape). Creating a fence was also counted as one move (although to do this one must click and drag).

Using efficient copying strategies did save time. The total time taken was negatively correlated with the proportion of moves where multiple items were worked with at once ($r_s = -0.672$, $p < 0.001$). Only three participants visited the on-line help facility, for less than forty seconds each, so these results are not included in the analyses.

For analysis, participants were split into high and low experience groups based upon the experience questionnaire data, and also high and low strategic-knowledge groups based upon the pre-test strategy

score achieved. The main analysis used was a between subjects 2x2x2 ANOVA with task type, experience and strategic knowledge as factors.

Task Type

Total Moves Those in the no-higher-goal condition ($M=116.8$) made fewer moves in total than the higher-goal condition ($M=323.2$) [$F(1,16)=51.168$, $p < 0.001$, $MSE=7916.1$], and took fewer moves to make each item ($M=0.6$) than those in the higher-goal condition ($M=1.9$) [$F(1,16)=37.444$, $p < 0.001$, $MSE=0.4$].

Excess Moves as a Proportion of Total Moves The fact that there were fewer moves made in the no-higher-goal condition may have been due either to reduced opportunity or to task focus. In order to further investigate strategy change as a function of opportunity we analyzed the excess moves as a proportion of total moves. For each task type the mean optimal number of moves was calculated (145 for higher-goal; 46 for no-higher-goal) and subtracted from each participants total number of moves to give the excess moves. The excess moves as a proportion of the total moves made was then calculated for each participant. There was no significant difference between the higher-goal group ($M=0.45$) and the no-higher-goal group ($M=0.49$) [$F(1,16)=0.363$, $p=0.555$, $MSE=0.05$].

Strategy Generation Higher goal constraints impacted upon how soon strategies were generated. Participants occasionally started to complete the task by working with individual shapes. Most however started working with one item (computer or a desk) at a time. A better strategy was to work with more than one item at a time. The move on which this strategy was first used was recorded. The higher-goal condition ($M=197.9$) worked with more than one item significantly later on than those in the no-higher-goal condition ($M=41.0$), $F(1,16)=18.729$, $p < 0.001$, $MSE=17227.6$.

The final progression in strategy use was to use an exponential copying strategy. A main effect of task type on the move when this strategy was first used was found [$F(1,16)=13.820$, $p < 0.01$, $MSE=21072.3$]; those with a higher goal ($M=229.8$) generated the strategy later on than those with no higher goal ($M=85.2$).

However, while in both tasks the earliest opportunity to use each of the strategies was the same (move 7), the overall opportunity to use the strategies differed between tasks. These results may therefore reflect either reduced opportunity or a different task focus.

Experience

At the start of the experiment participants had either no experience, or very little experience, with the drawing functions in Microsoft PowerPoint.

Table 1: Interaction between task type and experience.

Measure	High-Experience		Low-Experience	
	Higher-Goal	No-Higher-Goal	Higher-Goal	No-Higher-Goal
Total time taken to complete the task	1060.5	384.3	1630.7	458.2
Total moves taken to complete the task	279.0	116.0	750.0	118.0

Performance A median split placed participants in either a high-experience or low-experience group, based upon their experience questionnaire score.

A main effect of experience on time taken to perform the task was found [$F(1,16)=18.102$, $p<0.001$, $MSE=57457.4$]. Unsurprisingly those with high experience ($M=696.4s$) performed the task faster than those with low experience ($M=1097.7s$). High-experience participants ($M=191.2$) also performed the task using fewer moves than those in the low-experience group ($M=254.0$), $F(1,16)=9.395$, $p<0.01$, $MSE=7916.1$.

Strategy Generation More interestingly, experience had an effect on how soon efficient strategies were generated. There was a main effect of experience on the move participants first worked with multiple items [$F(1,16)=7.024$, $p<0.05$, $MSE=17227.6$]. High-experience participants generated this strategy ($M=87.1$) earlier than those who had low experience ($M=157.7$). Those with high experience ($M=122.2$) also generated the exponential copying strategy earlier than those with low experience ($M=199.3$), $F(1,16)=5.856$, $p<0.05$, $MSE=21072.3$.

Strategic Knowledge

Performance A median split placed participants in either a high-strategic-knowledge or low-strategic-knowledge group, based upon their pre-test strategy score. A main effect of strategic knowledge [$F(1,16)=19.321$, $p<0.001$, $MSE=7916.1$] found that high-knowledge participants ($M=199.3$) performed the task using fewer moves than those in the low-knowledge group ($M=240.8$).

Interactions

There was a significant interaction between experience and task type for the total time taken to perform the task [$F(1,16)=12.906$, $p<0.01$, $MSE=57457.4$] and also for the total number of moves taken to perform the task [$F(1,16)=7.956$, $p<0.05$, $MSE=7916.1$] (see Table 1). Simple effects tests revealed that where experience was low, the presence of higher goal constraints had an effect on the time taken [$FB@a2(1,16)=6.575$, $p<0.05$] and moves made [$FB@a2(1,16)=11.457$, $p<0.05$]. Simple effects tests also found that experience had a greater effect on time taken [$FA@b1(1,16)=8.350$, $p<0.05$] and moves made [$FA@b1(1,16)=12.382$,

$p<0.05$] where participants were given a higher goal. However, this interaction may have been due to a ceiling effect in the performance of the no-higher-goal condition.

Similarly there was an interaction between task type and strategic knowledge (see Table 2) for the number of moves taken to complete the task [$F(1,16)=7.544$, $p<0.05$, $MSE=7916.1$]. Simple effects tests revealed that strategic knowledge had a greater effect where participants were given a higher goal to consider [$FA@b1(1,16)=4.509$, $p<0.05$]. However, again this interaction may be due to a ceiling effect.

Table 2: Total moves taken to complete the task.

	High-Strategic-Knowledge	Low-Strategic-Knowledge
Higher-Goal	262.6	444.3
No-Higher-Goal	72.5	139.0

Spatial IQ

A regression found that spatial IQ had a significant influence on the total number of deletes and undos used by a participant, ($\beta=-0.477$, $p<0.05$). This suggests that those with a high spatial IQ perform the task more accurately than those with a low spatial IQ, and therefore do not need to undo or delete as often. Those with a high spatial IQ may be better able to plan their actions, and so make fewer mistakes.

Mental Representation of the Device

The amount of experience a participant had on other drawing packages had a significant influence on their first device representation questionnaire score ($\beta=0.554$, $p<0.01$). A regression found that a participant's score on the first device representation questionnaire (DRQ) had a significant influence on the time taken to perform the pre-test ($\beta=-0.484$, $p<0.05$). The score that participants gained on the first DRQ also exerted influence on early improvement in the number of moves made to make each item in the main task ($\beta=0.611$, $p<0.01$).

From these data we can suggest that previous experience allows more accurate hypotheses about the operation of the device to be developed while the participant answers the questionnaire. This representation then supports the generation of faster and more efficient methods.

Case Study

One case study demonstrated a particularly strong effect of having a higher goal. Initially the participant had low device knowledge, but had an average spatial IQ and previous experience with computer packages. The participant completed the pre-test task very quickly and used a very good strategy. The strategy used in the pre-test involved the participant fencing, copying and pasting four items at once. However during the main task where the participant had to design the layout of the computer room and study areas, he did not use this strategy or the exponential copying strategy. Instead he fenced, copied and pasted each item one by one, this taking him 417 moves ($M=220$) and 1465 seconds ($M=880$). In this case it seems that the presence of a higher goal actually inhibited the use of a known and previously used strategy.

Discussion

When higher goal constraints were present participants made more moves and generated new strategies more slowly. Those with higher goal constraints made at least four times as many moves before generating more efficient strategies. In addition, those with low strategic knowledge or experience suffered diminished performance and took nearly twice as long to generate efficient strategies.

Our analysis indicated that the effect of higher goal constraints was entirely due to the way in which the design task reduced the opportunity for the use of the more efficient strategies. Once opportunity was accounted for, higher goal constraints had no significant effect on the number of moves made. This suggests that higher goal constraints might not change the ability of a user to generate an efficient strategy, rather they may change the problem such that the opportunity to use efficient strategies is reduced. Users with a higher goal may have demonstrated adaptivity to opportunity.

As opportunity could account for the difference in performance between the higher-goal and no-higher-goal conditions, we found no evidence that a higher work goal might inhibit strategy generation. We found no support for the hypothesis that users become so focused on meeting higher goal constraints that they do not concern themselves with the efficiency of the methods by which they complete the task. However, further study is required to assess the extent to which strategy generation might be inhibited by focus on higher goal constraints when opportunity is held constant.

We also found no evidence that higher goal constraints inhibited users from taking time out to learn about the device (following from Carroll and Rosson, 1987), as participants very rarely used the on-line help and all groups concluded the experiment with similar

levels of device knowledge. More importantly, all the strategies were composed of the same known component procedures.

While the rate at which participants generated new strategies was slowed by a reduction in opportunity in the higher-goal condition, most participants showed a marked improvement in the efficiency of the strategies that they were using as the experiment progressed. Further, as participants made little use of the on-line help and did not stop performing the task to explore the package, the acquisition of device knowledge must have occurred while the task was being completed.

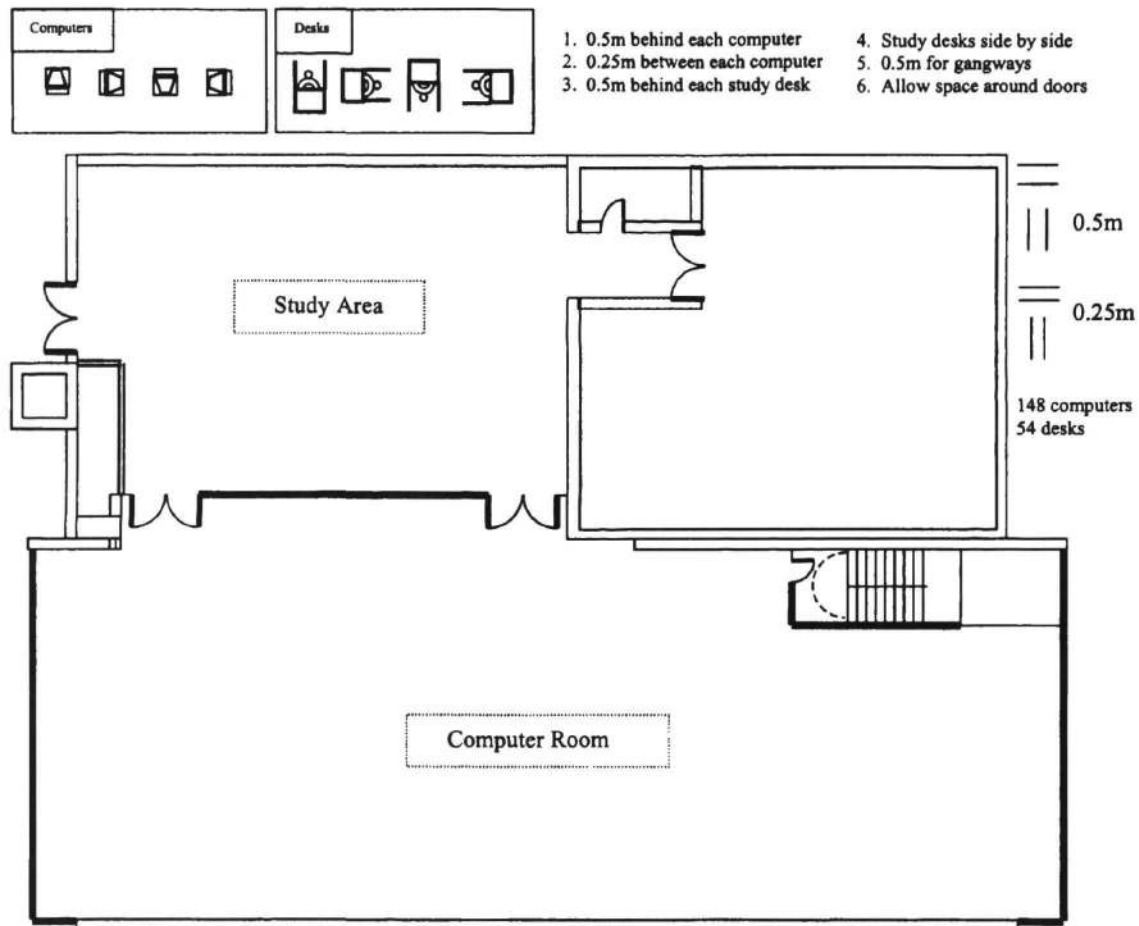

Together, our results suggest that it may be necessary to qualify the claim that people are unwilling to take time out to learn (Carroll and Rosson, 1987). Our findings, while laboratory bound, indicate that people are willing to invest in the generation of more efficient strategies within the bounds of what they discover while using the device. They may not go to a manual, but they do think about the way that they achieve tasks, they do attempt to explain what they observe, and they do adapt their methods accordingly.

Finally, our findings suggest that Bhavnani, John and Flemming's (1999) conclusion that people do not generate efficient strategies without instruction may be premature. Our participants generated efficient strategies within the bounds of what the higher goal constraints allowed. These findings suggest that it may be beneficial, instead of teaching strategies explicitly, to encourage strategy generation during task performance. While Bhavnani, John and Flemming (1999) argue that strategies need to be taught, it may be better, in the long term, to ensure that users actually generate the strategy themselves. Evidence in the psychological literature suggests that there are substantial advantages to self-generation and self-explanation (Chi, Bassok, Lewis, Reimann and Glaser, 1989; Bielaczyc, Pirolli and Brown, 1995).

Abstract

Categories are learned in many ways, but the focus of much category learning research has been on classification learning. In classification learning, the diagnosticity of features is a primary influence on learning and the category representation. In this paper, we assess this influence of diagnosticity on a different means of category learning, inference learning. In two experiments, each with a different dependent measure, we found the expected result that classification learning led to strong sensitivity to the diagnosticity of the features, even to the exclusion of prototypicality (when controlled for diagnosticity). However, inference learners were significantly less sensitive to the diagnostic value of the features, and were sensitive to the prototypicality. This result provides further evidence for the idea that different types of category learning differentially influence the category representation and provides a better understanding of inference learning.

Introduction

Categories are critical for a wide variety of cognitive tasks, such as classification, inference, explanation, communication, and problem solving. Category learning reflects how it is that people acquire knowledge of the categories that will successfully support these uses. Any intelligent system that extends information from specific examples to other related occurrences needs to account for the processes related to category learning. Thus, developing an understanding of category learning is an important research endeavor in cognitive science.

Although categories may be learned in a number of ways, the focus of category learning research has been on classification, how items are assigned to categories (e.g., Kruschke, 1992; Medin & Schaffer, 1978; Nosofsky, 1986). In classification learning, a subject is shown an item, asked to indicate its category membership (usually from a set of two possible categories), given feedback on their choice, and then allowed to study the item before the next item is presented. Through the learning trials of this classification task, the subject learns what items go into what category, thus developing a category representation that can be used later to answer questions about the category members or to classify novel items.

Category learning, however, does not just consist of classification learning. We learn categories for a variety of purposes, and how we learn categories is often tied to these uses. Category learning is based on not just classification, but on inference or explanation or problem solving (among other possibilities). A complete understanding of category learning requires considering additional category learning tasks and how they influence the category representation.

The idea underlying this research is that different ways of learning about categories lead to different category representations, and that our real-world representations often derive from a variety of ways in which categories are learned and used. Although this notion has a certain intuitive appeal, only a small number of category learning studies have examined it.

One category learning task that has received attention over the last few years is inference learning (Anderson, Ross & Chin-Parker, 2002; Yamauchi, Love & Markman, 2002; Yamauchi & Markman, 1998, 2000). In this task, a classified item is presented with a category feature missing and the task of the learner is to choose the appropriate feature for that item. For example, if one were making inferences about different types of birds, one might be given a classified bird (e.g., yellow-rumped warbler) with a number of its features and asked to choose its food preference. Inference is a critical component of category use. Since people learn about categories as they make inferences and receive feedback on their predictions, inference learning is a natural direction to follow in category learning research. This task has also been the focus of recent research because it has many similarities to classification learning and is formally equivalent to classification if the category label is treated simply as another feature (Yamauchi & Markman, 1998).

Diagnosticity

A critical aspect of current theories of classification learning is the focus on the *diagnosticity* of the features, how predictive they are of category membership (Tversky, 1977). As people learn to classify category members, they learn to attend more to those features that help to distinguish the categories (e.g., Kruschke, 1992). In the simple case in which the categories may be distinguished on the basis of a single feature, all the attention may be focused on that feature. For more complex cases, the attention is distributed across the diagnostic features to maximize classification performance.

Inference learning, however, may not lead to such an exclusive attention to diagnostic features. In inference learning, the item is already classified, so the learner can focus on *that* category and what features occur with members of that category. This focus on a single category at a time makes information about the prototypical feature values more available (Anderson et al., 2002; Yamauchi & Markman, 1998, 2000). This information about the prototypical feature values for each category means that the category representation emphasizes the internal structure of the category, what it is that coheres the members of the

category. This focus during inference learning suggests that different information about the category would be acquired during learning when compared to classification learning.

Current Experiments

The goal of the current experiments is to investigate the role of diagnosticity in category learning with two different category learning tasks, classification and inference. Based on a large body of previous research, we expect that diagnosticity will be the primary influence in classification learning. Thus, the question of most interest is how inference learning is affected by feature diagnosticity (versus the internal structure of the category). The hypothesis is that inference learning will not lead to as strong an influence of diagnosticity as does classification learning. This hypothesis is of importance for two reasons. First, it questions a major assumption of current models of category learning, that the diagnosticity of features is the most important determinant of category learning. Second, it helps to provide a further understanding of another type of category learning, inference learning.

We used a common category structure, family resemblance, as shown in Table 1. In this structure, the prototype is chosen and the learning items from that category consist of items that are similar to the prototype, though they may be different from one another. In the experiments reported here, all the learning exemplars match the prototype on all but one of the features.

The diagnosticity of the features is manipulated by varying the overlap of the prototypes. With this manipulation, to be described in detail for each experiment, we could separately vary the prototypicality of the item (i.e., how similar it was to the prototype, reflecting the internal structure) and the diagnosticity of the features (in terms of how predictive they were of category membership, reflecting the relation of the two categories).

Based on results from previous studies, we can anticipate some of the results of these experiments. Classification learners should show a strong effect of diagnosticity, but not prototypicality. We also know the inference learners should show a sensitivity to prototypicality. The question remains to be answered as to whether the inference learners will show any effect of diagnosticity. If they do show a sensitivity to diagnosticity, it should be significantly less than that of the classification learners.

Experiment 1

Experiment 1 investigated the influence of diagnosticity on classification and inference learning with a forced-choice test at transfer. The critical test trials varied the diagnosticity and typicality to examine the influence of the learning conditions. The categories learned were fictional "bugs".

The manipulation of diagnosticity as a function of prototype overlap can be seen in Table 1. The target category is the one on the left, the Deegers (prototype 11111, indicating a particular set of values for each of the five binary dimensions). Along with this category, subjects either learned the Lokads (prototype 00011) or the Koozles (prototype 11000). Those features common to both prototypes are not diagnostic because they do not help one

Table 1: Category Structure for Experiment 1.

	Deeger	Lokad	Koozle
Learning Exemplars	11110 11101 11011 10111 01111	00010 00001 00111 01011 10011	11001 11010 11100 10000 01000
Prototype	11111	00011	11000

to determine category membership. As can be seen, both contrast categories overlapped Deegers on two features, but two different features. Thus, for subjects learning Deegers and Lokads, the last two features were not diagnostic, whereas the first two were not diagnostic for the subjects learning Deegers and Koozles. By varying the test features for Deegers, we can determine the extent to which diagnosticity is being used, as described shortly.

Method

Design There were two learning conditions, classification learning and inference learning. Within each learning condition half of the subjects learned about Deegers and Lokads, and the other half learned about Deegers and Koozles. The position of the bug attributes within the category structure was balanced across subjects. This resulted in a total of ten experimental groups. Within the study and transfer blocks, items were randomly presented.

Subjects Fifty undergraduates from the University of Illinois participated for either course credit or pay. Ten subjects who did not meet the learning criterion (two classification, eight inference) were replaced.

Materials The materials were drawings of "bugs" labeled Deegers, Lokads or Koozles (see Figure 1). These bugs varied along the binary attributes of their antenna, legs, tail, body coloring and eyes.

Each subject learned two categories, the target category (Deegers) and one of the two non-target categories (either Koozles or Lokads). The abstract structures for the three categories can be found in Table 1. Each of the non-target category prototypes overlapped with the target category prototype on two features. The features that overlapped were

Figure 1: Example Prototypes for Bug Categories in Experiment One

not predictive of category membership as they occurred equally often in each category. The remaining three features were diagnostic in that they occurred 80% of the time with one of the categories. Whether a particular feature was an overlap or diagnostic feature depended on which of the two non-target categories was learned with the Deeger category. For example, the Deeger specified by 11110 was seen by all subjects during learning. For a subject that learned the Lokad category along with the Deeger category, the first feature was a diagnostic feature, in that it was consistent with the Deeger prototype but not the Lokad prototype. For a subject that learned the Koozle category along with the Deeger category, the first feature was an overlap feature because it occurred in both the Koozle and Deeger prototypes. This design of the category structures allowed the same item to vary in terms of its diagnosticity between subjects, depending only on the category set learned, while the item prototypicality remained constant.

Table 2 specifies the terminology used to describe the bugs. The bugs varied on two dimensions, their relation to the category prototype (prototypicality) and the number of diagnostic features maintained. Along the first dimension, there were three possible levels: prototype, typical and atypical, which indicated whether there were 5, 4, or 3 features consistent with the prototype. For the second dimension, the item could maintain 1, 2, or 3 of the diagnostic features. For a subject that learned the Deeger-Lokad combination, 11110 would be a typ3 Deeger: it is typical because it has four features consistent with the prototype 11111, and it has a diagnosticity of 3 because it has all three of the diagnostic features for Deeger (111--). However, for a subject that learned the Deeger-Koozle combination, 11110 would be a typ2 Deeger: again it is typical because it has four of the prototype features, but now it only has 2 of the diagnostic features (--111).

The study items were the five typical bugs for each category being learned. For the classification subjects, these bugs were always seen complete. In the inference condition, the bugs were missing one feature that was consistent with the prototype. The inference subjects also saw the two possible features that were choices for the missing feature.

The transfer items were pairs of bugs from a given category. There were two critical types that allowed an examination of the influence of diagnosticity: typ/typ and typ/atyp items. The six typ/typ transfer items were pairs of bugs that were matched in prototypicality (both were typical) but varied in the number of diagnostic features. One of the bugs in the pair would be a typ2, while the other was a typ3, the specification being dependent on which category

set had been learned. The typ/atyp pairings varied both in terms of how many features were consistent with the category prototype and the number of diagnostic features. Of the six typ/atyp transfer items, three of the pairs consisted of a typ2 and an atyp3. These transfer items pitted typicality to the category prototype against the diagnosticity of the features. The other three pairs consisted of a typ3 and an atyp1. For these pairs, both typicality and diagnosticity were in agreement as to which bug was the better category member. The content of the typ/atyp pairs was also dependent on the category set learned; the typ2/atyp3 pair for someone who learned Deeger-Koozle was the typ3/atyp1 pair for someone who learned the Deeger-Lokad set, and vice-versa. The critical typ/atyp pairs are the typ2/atyp3, but the typ3/atyp1 pairs allow full counterbalancing of items.

There were nine additional filler transfer pairs in the Deeger task, as well as 12 pairs for the other category that did not address the issues of interest.

Procedure Subjects were given verbal instructions prior to the study phase. All subsequent instructions and reminders appeared on the computer screen. Learning and testing were done on Macintosh computers using Psyscope (Cohen, MacWhinney, Flatt, & Provost, 1993). All subjects were debriefed both verbally and with a written statement as to the general intent of the experiment.

In the classification condition, subjects saw a bug presented in the center of the screen. Subjects indicated which category they thought the bug belonged to by pressing the "D" key for Deeger, the "K" key for Koozle or the "L" key for Lokad. Feedback was given as to whether the choice was correct or incorrect, and the subject was shown the bug again along with the correct name to study. This study time was self-paced. The learning phase continued for a minimum of four blocks, ten exemplars per block, until the subject was able to correctly identify nine of the ten bugs within a block.

In the inference condition, the subjects were presented with an incomplete bug (one of the five attributes was absent from the bug picture) centered on the screen. The category label was presented to the left of the bug, and the two possible features for the missing attribute were presented on the right side of the screen, one above the other. The subject indicated a choice by clicking the mouse on one of the two features. The position of the correct feature was randomized across learning trials. Feedback was given, and self-paced study time was allowed. The learning criteria were the same as in the classification condition.

Following learning, all subjects completed the same forced choice test. No feedback was given to the subjects during the transfer phase. Each subject completed the target (Deeger) test first. Subjects saw two possible Deegers on the screen, one centered on the right-hand side of the screen and the other centered on the left-hand side of the screen. Below the pictures appeared the question, "Which of these bugs is most typical of a Deeger?" Once the subject clicked on one of the pictures, a box appeared around the choice and the prior question was replaced by "How confident are you of your choice?" along with a number scale going from one (guessing) to seven (very sure). The subject clicked on a

Table 2: Abbreviations for Items

	# of Prototype Consistent Features	# of Diagnostic Features Maintained
Proto	5	3
Typ3	4	3
Typ2	4	2
Atyp3	3	3

Atyp1	3	1

number to indicate his or her confidence. Once the target category transfer was completed, the subject was informed that the same type of questions would be asked about the other bug category. The procedure for the non-target category transfer was identical.

Results and Discussion

For the typ/typ transfer items, the mean proportion of choice for the typ3 Deeger was calculated. Also, the mean confidence scores were determined; confidence scores when selecting the typ2 were multiplied by -1 (no preference between the bugs would result in a mean confidence of zero). These results examine how important the diagnosticity was to each condition when the prototypicality is held constant. The classification learners chose the bug with more diagnostic features well above chance ($m = .79$), $t(19) = 4.74$, $p < .01$, while the inference learners did not ($m = .56$), $t(19) < 1$. These results are also reflected in the group confidence ratings. The classification learners' confidence rating ($m = 3.44$) was significantly greater than 0, $t(19) = 5.38$, $p < .01$, while the inference mean confidence rating ($m = 0.70$), was not, $t(19) = 1.22$, $p > .10$. The proportion of the classification learners who chose the typ3 bug over the typ2 bug was significantly greater than the proportion of inference learners, $t(38) = 2.70$, $p < .01$. The mean confidence score of the classification learners was also significantly different from the score of the inference learners, $t(38) = 3.19$, $p < .01$.

For the typ/atyp items, the mean proportion of times the typical Deeger was chosen over the atypical Deeger was determined. The mean confidence rating was calculated by multiplying the confidence scores when choosing the atypical bug by -1 . Of interest are the bug pairs that pitted typicality against diagnosticity, the typ2/atyp3 pairs; choosing the typ2 bug meant that overall typicality to the prototype was of primary importance while choosing the atyp3 bug indicated that diagnosticity was driving the decision. The classification learners chose the typ2 bug ($m = .35$) marginally less than the inference learners ($m = .57$), $t(38) = 1.81$, $p < .10$. However, the mean confidence score for the classification learners (-2.22) was significantly lower than that of the inference learners (0.76), $t(38) = 2.49$, $p < .05$.

For both transfer measures, the typ/typ and typ/atyp items, the classification learners showed significantly more dependence on diagnostic information than the inference learners when making decisions about the category members. In the typ/typ measure, the inference learners did not show an influence of diagnosticity. The typ/atyp results are more difficult to assess in this regard since there is no clear baseline to compare performance to. These results show a clear difference in the role of diagnosticity for the two different types of category learning.

Experiment 2

Experiment 2 examined the same issues, but had three differences from Experiment 1 to increase generality and the number of critical observations. First, during transfer, a typicality rating task was used rather than a forced-choice task. Second, to allow us to use all the transfer data to test

Table 3: Category Structure for Experiment 2

	Deeger	Lokad	Koozle	Himlit
Learning	11110	00010	11001	10100
Exemplars	11101	00001	11010	10111
	11011	00111	11100	10001
	10111	01011	10000	11101
	01111	10011	01000	00101
Prototype	11111	00011	11000	10101

the hypothesis, we changed the design so that each category had a critical contrast (see Table 3). As before, one subject might learn Deegers and Lokads, whereas another learned Deegers and Koozles. However, by adding two more counterbalancing groups (Himlit and Lokads, Himlit and Koozles), all the categories had critical test items. Third, although the items were again fictitious bugs, new features were constructed.

Method

Design As in Experiment 1, there were a classification and an inference condition. There were four possible category combinations a subject could learn [Deeger-Koozle, Deeger-Lokad, Himlit-Koozle, Himlit-Lokad]. Within each possible combination, there was a balancing as to the order of the categories presented during the typicality rating task. The presentation of items within both study and transfer blocks was random.

Subjects Sixty-one undergraduates from the University of Illinois participated for either course credit or pay. One subject's data were lost due to a computer error and 12 subjects (five inference, seven classification) were replaced who did not meet the learning criterion.

Materials The materials for this experiment were again drawings of "bugs" (Deegers, Himlits, Koozles and Lokads) that consisted of five binary attributes: legs, wing, eyes, antenna, and tail. Across subjects, each attribute was balanced as to whether it served as an overlap or diagnostic attribute. The bugs seen during learning were the five typical bugs (one feature of each was not consistent with the prototype) from each of the two categories being learned, and they were presented as in Experiment 1.

The typicality rating task consisted of 16 bugs for each category learned. Five of the bugs were the typical bugs (one inconsistent feature each) which had been seen during learning. The other 11 bugs were novel to the subject at the time of the typicality rating task. These bugs consisted of the category prototype along with 10 atypical bugs, each of which had two features that were inconsistent with the prototype. The levels of prototypicality and diagnosticity were specified as in Experiment 1 (refer to Table 2).

Procedure The procedures during the learning phase for this experiment were very similar to those in Experiment 1. The primary differences were that the classification subjects used the mouse to click on the category label and the study time

was restricted to two seconds per bug. The learning criteria were the same as Experiment 1.

Following the learning phase, the subjects were given instructions on the computer screen explaining the typicality rating task. During this task, a single bug appeared centered on the screen along with the question, "How typical is this bug of a [Deeger, Himlit, Koozle, Lokad]?" Underneath the picture were the numbers from one ("Not at all typical") to seven ("Very typical"). The subject indicated their rating of each bug by clicking the mouse on one of the numbers.

Results and Discussion

What influences the typicality ratings for the two learning groups: diagnosticity, prototypicality or both? The short answer is that the ratings of classification learners were influenced only by diagnosticity, whereas both diagnosticity and prototypicality affected the ratings of the inference learners.

The group means for each of the bug types are provided in Table 4. The effect of diagnosticity becomes clear when the column means are examined. Collapsing across the levels of prototypicality, it is evident that classification learners showed a large effect of diagnosticity, whereas inference learners showed some effect, but a smaller one. The ANOVA supports this interpretation with no main effect of learning, $F(1, 46) < 1$, a significant main effect of diagnosticity, $F(2, 92) = 147.87$, $p < .001$, and an interaction between the factors, $F(2, 92) = 13.17$, $p < .001$. As can be seen at the column mean level (and also within each row), the loss of a diagnostic feature reduced typicality ratings almost 1.5 (on a 1-7 scale) for the classification learners, whereas it had much less of an effect on inference learners.

The effect of prototypicality requires a more careful examination. Collapsing over the diagnosticity levels, the two learning conditions show very similar row means, supported by the ANOVA indicating that there is no main effect of learning condition, $F(1, 46) < 1$, a significant effect

of prototypicality, $F(2, 92) = 102.96$, $p < .001$, and no interaction between the two, $F(2, 92) < 1$. However, the difference between conditions is hidden by the fact that prototypicality in this analysis is confounded with diagnosticity as can be seen in Table 4. For classification learners, within each column there is no effect of prototypicality. For example, as long as the item has all three diagnostic features, the rating given by the classification learners does not depend at all on whether it has the two non-diagnostic features consistent with the prototype (prototype, 5.92), just one of them (typical, 5.98), or neither of them (atypical, 5.88). A similar result is seen with the items that maintained two diagnostic features; on average, the classification learners actually rated the atypical items 0.12 higher than the typical items. However, inference learners show large effects of prototypicality at each level of diagnosticity. For the test items with all three diagnostic features, each non-diagnostic feature makes a difference of about 0.7. The inference learners dropped their typicality rating about 0.9 when a non-diagnostic feature was removed from the items that maintained two diagnostic features.

Thus, in Experiment 2, the typicality ratings of classification learners were influenced only by diagnosticity, whereas both diagnosticity and prototypicality affected the ratings of inference learners.

General Discussion

The diagnosticity of features plays a critical role in current theories of category learning. These experiments investigated the role of diagnosticity for two different means of category learning, classification and inference, and found an important difference. For both experiments, classification learners relied on the diagnostic features when making decisions about category members. Inference learners were sensitive to both the diagnosticity of the features (although much less so than the classification learners) and the relationship of the item to the category prototype. These results indicate that these two different ways of category learning lead to different emphases in the category representation. Yamauchi, Love, and Markman (2002), using a non-linearly separable category structure, also found that inference learners did not show an effect of feature diagnosticity, while the classification learners did, when predicting missing features of items following learning.

The results of this study rule out the strong hypothesis that the inference learners would not be at all sensitive to the diagnostic value of the features. However, this conclusion needs to await further research for two reasons. First, there were only two categories, so the probability that cross-category comparisons might be made (e.g., about the internal structure learned by inference) was probably much greater than in many more realistic situations. When we learn about items there is normally not such an obvious and closely related contrasting category being learned. Second, it is possible that some or all of this influence occurred at test. For example, the effect of diagnosticity in inference learning was most evident when the items were less typical category members. Since these items would have had more features in common with the non-target category, their presence may

Table 4: Mean Typicality Ratings from Experiment 2
Classification Learners

	Number of Diagnostic Features			
	3	2	1	mean
Prototype	5.92	—	—	5.92
Typical	5.98	4.39	—	5.02
Atypical	5.88	4.51	2.93	4.18
	5.94	4.47	2.93	

Inference Learners

	Number of Diagnostic Features			
	3	2	1	mean
Prototype	6.06	—	—	6.06
Typical	5.24	4.98	—	5.08
Atypical	4.63	4.07	3.66	4.00
	5.29	4.37	3.66	

have prompted the inference learners to consider that other category (although it was not necessary to do given the design of the transfer tasks). Again, this seems to be much less likely in more realistic category situations. It is important to keep in mind that although the inference learners did show some sensitivity to the diagnosticity of the features, it was sometimes tiny and always significantly less than the classification learners. Despite these possibilities, it is important that future research more fully examine how the category representation is influenced by inference learning.

It is also interesting to consider the classification learners. Their lack of sensitivity to the non-diagnostic features that were part of the prototype suggests an extreme focus in the representation they develop. Other results also point out some difficulties that arise from category learning based solely on classification. Yamauchi and Markman (1998, Exp. 2) found that varying the order of classification and inference learning resulted in a situation where a block of classification learning prior to inference learning was not beneficial (although inference learning prior to classification learning was). Chin-Parker and Ross (in press) showed that classification learners were not sensitive to within-category correlations whereas inference learners were sensitive to this relational structure. Anderson et al. (2002) also found that classification learners were less accurate than inference learners when classifying individual features of category members. These lines of research suggest that classification learning may lead to a category representation that is good at determining category membership of items but is impoverished with regards to other category information.

The question remains as to why classification and inference learning lead to such different category representations. Even though the two learning tasks can be considered formally equivalent, they impose very different demands on the learner. In the classification learning task, a subject is shown an item and predicts the category label using the available information. If a piece of information is not diagnostic, such as "flying" when learning to distinguish birds and bats, it is not important and not incorporated into the category representation. The current experiments and formal modeling (Kruschke, 1992) have shown that diagnosticity is the primary concern during classification learning. As noted earlier, the inference learning task focuses the learner on a single category, promoting the acquisition of information about the internal structure of that category. This would make the inference subjects sensitive to what are the most likely features given the category membership. If an item is labeled as a "bird" and then a prediction is made about how it will get from one tree to another, the correct prediction would most likely be "flying", and that piece of information is incorporated into the category representation. Recognition of the features that distinguish birds from bats is not important in this situation, so those diagnostic features would not be made salient.

A major challenge now will be to formalize the differences that exist between the various means of category learning and to incorporate that information into a category learning model. Such a model would be useful for any

endeavor within the cognitive sciences concerned with learning from past experience.

In closing, it is important to remember that when we learn about categories in more realistic situations, it is by a combination of different tasks, such as classification, inference, and explanation. The limited representation that is developed as a result of classification learning does not appear to be much like the flexible, dynamic representations that underlie our knowledge of real world categories. However, the same may be true of a category representation that is developed as a result of any single category learning task. It may be the combination of various learning tasks that creates a flexible and dynamic representation. To understand category learning as it exists outside of the laboratory, we are going to have to develop a more integrated approach to category learning (e.g., Solomon, Medin, & Lynch, 1999).

Abstract

Comprehension monitoring and regulation in a distance learning situation were examined in comparison to individual learning through an error-detection paradigm. The collaborative learning condition produced significantly better learning and monitoring. These results were interpreted as the effect of regulative interaction in the collaboration. Then, the specific interactions of 3 good and 3 poor pairs were contrasted to examine their interaction pattern in terms of monitoring and regulation. The results showed that the good pairs had a higher level of monitoring and regulative interaction. Also when the good and poor groups successfully monitored comprehension failure, the poor groups implemented less effective regulation strategies.

To understand text, learners need to integrate successively encountered information from that text into a coherent and well-integrated (mental) representation (Kintsch, 1998). According to Kintsch this comprehension process proceeds in a piecemeal way, sequentially developing a bigger and more coherent representation. This process tends to be prone to errors such as representation of incorrect information and/or misrepresentation of correct information due to omissions, inconsistencies, and/or anomalous and unclear text. When these comprehension failures occur, learners should be able to use metacognitive monitoring to detect the failures and regulation strategies to repair them and thus construct a more coherent understanding of the text in order not to end with a lack of understanding or misunderstanding.

However, despite the significance of monitoring and regulation strategies to text understanding, learners tend to fail to detect their own misunderstandings (Markman, 1979), ignore incorrect information (Otero & Kintsch, 1992), and overestimate their own understandings (Glenberg, Wilkinson, & Epstein, 1982) and capabilities (Pressley & Ghatala, 1990). Learners are too often satisfied with their *faulty* understanding to challenge given tasks and hence fail to trigger regulation processes. Accordingly, various efforts such as metacognitive strategy training, setting up explicit comprehension goals, or self-generating feedback have been made to improve learners' comprehension.

Considering that effective learning often takes place in social settings, and that individual learners' comprehension could be affected by their peers' comprehension, it seems worthwhile to examine comprehension monitoring and regulation in collaborative learning situations. More

specifically, comprehension monitoring and regulation seem especially critical in distance collaboration situations where a lot of learning takes place from text. Therefore, the goals of this research are to examine whether distance collaboration improves individuals' comprehension monitoring and regulation abilities, as well as the conditions that make distance collaboration produce effective or ineffective text comprehension.

Monitoring and Regulation in Collaboration

Monitoring and regulation have been considered critical in effective face-to-face collaboration because they help learners construct a more coherent understanding. First, externalizing thinking and understanding through communication might help collaborators better monitor and regulate their performance (Miyake, 1997) because it causes thinking and understanding to become objects that can be sharable and manipulable between collaborators (Miyake, 1986). While learners working alone are often subject to self-confirmation bias, learners can benefit from working with peers thanks to a 'checking mechanism' in collaboration (Miyake, 1986) that advances comprehension monitoring and regulation. Second, the division of cognitive processes in collaboration (Dillenbourg, Baker, Blaye, & O'Malley, 1995) may play a part in improving monitoring and regulation in collaboration. For example, one peer might take the role of leader, while another peer might take the role of monitor (e.g. Miyake, 1986). In the process of collaboration, many errors made are detected and corrected by partners (Miyake, 1986; Resnick & Salmon, 1993). Also, Karabenick (1996) recently showed that learners may have better comprehension monitoring after receiving questions from colearners. Third, comprehension monitoring and regulation could be easily implemented when peers have conflicting perspectives. As Piaget's socio-cognitive conflict theory suggests, collaborating individuals with different understandings of the same task may advance their understanding in the process of resolving their differences. Fourth, regulating comprehension problems seems fundamental to collaboration processes because the regulation process in collaboration may be activated automatically (Schegloff, 1991), and incorrect elements of their representation might then be fixed through communicative interactions such as engaged discussion (Krugier, 1992), elaboration or arguments (van Bostel, van

der Linden, & Kanselaar, 2000), or other repairs (Lumpe & Staver, 1995).

Because collaborating learners may have higher chances of monitoring (detecting that there might be something wrong) and of regulation (knowing what could be correct knowledge), it might be straightforwardly expected that collaborating learners will have better comprehension than isolated learners. However, when distance between learners is involved in learning, the above inference seems complicated because people working together at a distance report various kinds of difficulties that seem to deteriorate collaboration. First, the lack of nonverbal communication cues in distance communications may torture clear communications (Armstrong & Cole, in press) that help to manipulate thinking. Second, distance learners have difficulty in grounding communications and spend a long time doing so (Kiesler, Siegel, McGuire, 1984). Third, some studies report that cognitive conflicts are not only well detected (Armstrong & Cole, in press), but also rather emotionally charged with no easy method of cognitive resolution. Finally, anonymous individuals who are placed in group distance learning situations tend to be less supportive of each other because of low perceptions of group cohesion and conformity.

Therefore, one could propose the following model of effective distance collaboration. When comprehension failures occur, they should be detected. If not, the failures might end up with non- or mis-comprehension. Once the failures are detected, they should be repaired. If not, the failures also might lead to non- or mis-comprehension. To test the model, we hypothesized that if interactions between individuals working at a distance (e-Pairs) are sufficiently effective, they will be better than the individuals working alone (Singles) in learning scores because of better comprehension monitoring and regulation and that good e-Pairs will be better than poor e-Pairs in comprehension monitoring and regulation.

Method

Comprehension monitoring and repairing during distance collaboration was compared to monitoring and repairing during individual learning. Unlike typical face-to-face collaboration studies that emphasize ecological validity, we wanted better experimental control and a wider range of data.

Participants. Sixty-nine undergraduates (Male = 27, Female = 42) taking introductory psychology courses volunteered in this study. All the participants received course credits for participation. The first language of all the subjects was English. They all reported that they had experience using chatting interfaces on the internet and were familiar with these interfaces. Randomly, thirty-seven of them were assigned to an individual learning condition (Singles: male=15, female=22) and the other 32 to the collaborative learning condition (e-Pairs: male=12,

female=20). All e-Pairs participants were randomly paired with a same sex partner. One pair was removed from the data analysis because of a problem with the interface.

Materials. Two expository texts about theories of knowledge representation were used. One text concerned symbolism and the other connectionism. The text content was selected because undergraduate students were not familiar with these theories of representation, and this allowed us to minimize the pre-knowledge effect and maximize the purity of comprehension monitoring and regulation strategies. Each text consisted of 15 sentences and had two versions: Consistent and inconsistent. Following Markman (1979)'s *error-detection paradigm*, inconsistent versions had contradictory or inconsistent information at the 5th, 10th and 15th sentences. For example, the first five sentences used in the symbolism text were (1) *One of the major theories about representation is called symbolic representation.* (2) *The symbolic representation view is that the human mind represents information as a language-like or symbolic form.* (3) *Because most of us think and all of us write linguistically, we tend to couch our ideas in symbols like a natural language form.* (4) *We can understand thought, belief, problem solving in a language-like symbolic form.* (5c) *Thus, in this view, symbols (roughly, words) are used to represent information in the human mind.* (5i) *Thus, in this view, symbols (roughly, words) are not used to represent information in the human mind.* Here the 5c was a consistent sentence, while 5i was an inconsistent sentence. Thus, when subjects came to read the fifth sentence, either (5c) or (5i) was displayed to them. Detecting the first inconsistent sentence located at the 5th position was manipulated to be the easiest, that of the second at 10th position the middle, and that of the last at the 15th position the most difficult in terms of the amount of correct representation needed to detect the inconsistency.

Interface. A computer interface (see Figure 1) was used to manage the experiment automatically, to collect data, and to provide an environment in which the participants could work. The interface for the main experiment session consisted of five units: (1) a new sentence display unit, (2) a history window, (3) a monitoring detection task unit, (4) a comprehension self-rating slider, and (5) an IRC (internet relay chatting) as a distance communication channel. The new sentence display unit was used for displaying each new sentence. When each new sentence appeared, the previous sentence moved up to be located at the bottom in the history window which accumulated all the previous sentences. Thus, the participants could focus on comprehension instead of memorizing sentences. The distance communication channel was an internet relay chatting interface where each pair communicated without any verbal and nonverbal interaction. The individual learning condition was identical except for not having the distance communication channel.

Figure 1: Computer interface

Comprehension monitoring task. There were two monitoring tasks: Detection and comprehension self-rating. The detection task was to decide whether or not each sentence was consistent with previous sentences. The self-rating of comprehension was measured with a rating scale labeled with 0%, 25%, 50%, 75%, and 100%, indicating the approximate percentage of the meaning that the subject believed he/she understood. However, self-rating measures appeared unreliable and were thus removed from the results.

Comprehension regulation interaction coding scheme. Each episode (the period between the end of one sentence and the start of the next new sentence), was evaluated in terms of the level of monitoring and regulation quality exhibited. The conversation levels were coded using the following hierarchical scheme: 0: off-task – coded when an episode consisted of task-unrelated things; 1: Checking answers – coded when an episode consisted only of asking for and providing each other's answers; 2: Rephrasing – coded when an episode consisted of providing answers and rephrasing the given sentence as their rationale; 3: Explanation – coded when an episode included integrating, relating, or generating information to explain answers; 4: Elaboration – coded when subjects proceeded to elaborate or clarify each other explanation, and 5: Negotiation – coded when an episode was resolved with an agreed cognitive solution. This scheme was hierarchical in that the higher, the better in comprehension as a continuum from low level monitoring (Checking answers) to high level regulative behavior (Negotiation). When multiple levels in an episode appeared together, the highest one was selected to represent the quality of interaction of the episode. Two coders independently coded two randomly selected groups for the analysis and achieved a 0.84 inter-coder reliability.

Procedure. Each participant was randomly assigned to either the Singles condition or the e-Pairs condition. The participants went through an instruction session, a pretest session where they answered 20 multiple choice questions about the main texts, a warm-up session that had two short texts to familiarize them with the interface, a 2nd instruction session that was exactly same as the 1st instruction, a main task session, and a posttest session. In the instructional

sessions, they read that they would study, with or without a partner, two draft texts that might or might not have inconsistent information. They were also instructed that they should explain the meaning of each sentence – to themselves in the Singles or with their peer in the e-Pairs – and that they would get bonus credits based on their performance. Both the pre- and post-test comprehension questions, and their alternatives about the main tasks, were completely randomized. In the main task session, all the participants in the e-Pairs were randomly paired with a same-sex partner with whom they had no interaction before the main task session. The order of presentation of the two texts was randomized and the selection of either version was counterbalanced. Thus, the participants studied two texts but only one of them was an inconsistent version. In each episode identified as each sentence level interaction, whenever a new sentence appeared, the participants individually read the sentence, performed the comprehension monitoring tasks (the detection and self-rating task) with no means of communication. Then they studied the sentence by explaining the meaning of the sentence either alone in the Singles or together with a peer through the distance interaction channel in the Pairs. When they decided to finish studying, they hit a button to request another sentence, at which point the communication channel was automatically disabled. These sentence level activities repeated until the end of the two tasks. Note that the e-Pairs were not asked to reach an agreement, did not have an interaction before the main task session, and only their first names were shown on the communication channel interface.

Results

1-1. e-Pairs will be better than Singles in learning

A one-way ANOVA showed no significant difference in the pretest scores between the Singles and e-Pairs. Another one-way ANOVA was done with the learning defined as the difference between the post- and pre-test scores. The e-Pairs ($M = 4.47$, $SD = 1.73$) were significantly better than the Singles ($M = 2.62$, $SD = 1.88$) ($F(1,65) = 5.13$, $p = .03$). Finally, the effect size as *Cohen's d* was 1.02. These results provided a rationale to conduct further analyses.

1-2. e-Pairs will be better than Singles in monitoring

The detection task performance as comprehension monitoring was examined (see Figure 2). In the consistent versions, the e-Pairs ($M = .92$, $SD = .06$) and Singles ($M = .88$, $SD = .04$) were not significantly different on any sentence. However, in the inconsistent versions, the e-Pairs were significantly better for the first inconsistent sentences, the easiest one (5th sentence: for e-Pairs $M = .75$, $SD = .18$; for Singles $M = .18$, $SD = .01$) at text 1: $F(1,32) = 18.03$, $p = .00$ and at text 2: $F(1,33) = 5.05$, $p = .02$, not for the second (10th) and the third (15th) inconsistent sentence.

2-1. Good e-Pairs will be better in monitoring

To examine what mechanisms drive effective distance collaboration, three good ($M = 13.3$, $SD = 2.1$) and three poor e-Pairs ($M = 4.0$, $SD = 7.0$) were selected, $t(4) = 5.74$, $p = .00$. This selection was made after removing e-pairs where peers had large knowledge differences, to avoid looking at extreme cases. No significant differences between the good and poor Pairs were found in the pretest scores (Good: $M = 11.0$, $SD = 2.0$; Poor: $M = 13.0$, $SD = 5.6$), the pretest difference between members in each pair (Good: $M = 1.0$, $SD = 0$; Poor: $M = 1.0$, $SD = 1.0$), the mean number of turns per episode (Good: $M = 6.7$, $SD = 3.3$; Poor: $M = 6.4$, $SD = 5.0$), the total time spent per group (Good: $M = 52.7$ min, $SD = 15.0$; Poor: $M = 47.2$, $SD = 14.3$), and time per episode (Good: $M = 1.76$ min, $SD = .5$; Poor: $M = 1.6$, $SD = .5$). These non-significant indices formed the baseline against which to examine differences in the level of monitoring and regulation quality in collaboration.

Figure 2. Comprehension monitoring task performance

Then, the hypothesis that high e-Pairs will be better in comprehension monitoring was tested. There were no significant differences at all three inconsistent sentences, although the pattern looks similar to that of the comparison between the e-Pairs and Singles.

Figure 3. Quality of regulative interaction in general

2-2. Good e-Pairs will have higher quality of monitoring and regulative interaction than poor e-Pairs

Another difference was found in the level of monitoring and regulation quality in their interaction. The good e-Pairs ($M = 2.77$, $SD = .97$) had a significantly higher level of regulative interactions than the poor e-Pairs ($M = 1.64$, $SD =$

1.0), $F(1,178) = 58.40$, $p = .00$ (see Figure 3). In general, the good e-Pairs interaction quality was around explanation level, whereas the poor e-Pairs interaction quality was between just checking answer and rephrasing (refer to coding scheme in the method section).

2-3. Given successful monitoring, good e-Pairs will be better than poor e-Pairs in regulative interaction.

Before answering the question, we examined when e-Pairs had longer conversations, which means they tried to do something more like repairing. Based on each individual decision on the detection task before starting each interaction period, each episode was categorized into one of three categories: both members' answers or perspectives were 'same and correct', 'same and incorrect', or different. Then comparisons were made between good e-Pairs and poor e-Pairs. According to a two-way ANOVA ($F(2,174) = 8.2$, $p = .00$) and its Scheffe, the only significant difference was on the category dimension, especially between the level different and the others (see Table 1).

Table 1: The mean number (SD) of turns in episode

Categories	Good	Poor	Mean
Same & Correct	6.3 (3.1)	5.7 (4.8)	6.0 (4.0)
Same & Incorrect	5.0 (2.5)	6.8 (4.2)	6.0 (3.3)
Different	9.8 (3.0)	8.8 (4.9)	9.2 (4.3)
Mean	6.7 (3.3)	6.4 (5.0)	6.5 (4.1)

Figure 4: Quality of interaction given successful monitoring

Then we examined the hypothesis that good e-Pairs will have higher quality of interaction (see Figure 4). Regulative interaction qualities between the good and the poor e-Pairs were compared when they all had successful monitoring. Given the total 24 episodes (good: $n = 10$; poor: $n = 14$) where peers in an e-Pair had different perspectives that signaled there might be something wrong, their interaction qualities were examined. Interestingly, the poor e-Pairs ($M = 2.21$, $SD = 1.31$) showed a significantly lower level of regulative behavior than the good e-Pairs ($M = 3.60$, $SD = .52$), $F(1,23) = 9.95$, $p = .00$. The interaction quality of the good e-Pairs was between the explanation and elaboration

level, while that of the poor e-Pairs was around rephrasing. For example, the following episode from a good e-pair shows that when peers had different opinions they tried to resolve the difference.

- | | |
|---------|---|
| 1: Lao | i put incorrect b/c i had no clue what that was about |
| 2: Lao | sorry:(|
| 3: Cat | haha |
| 4: Cat | that's alright |
| 5: Lao | i just thought that the info sounded like conflicting symbols |
| 6: Cat | it's just saying that by adding another symbol to a sentence you can make it a fact |
| 7: Cat | the sentence is kinda weird |
| 8: Lao | oh ok |
| 9: Lao | yeah it is |
| 10: Cat | maybe the next sentence will be about displacement |
| 11: Lao | ok |

However, another episode from a poor e-pair shows that after they checked their answers they did not try to resolve their comprehension failure.

- | | |
|-------|---|
| 1: Cu | hmm |
| 2: Ja | i wasn't sure about this one |
| 3: Cu | me either |
| 4: Cu | I chose incorrect |
| 5: Ja | oh, i chose correct. i don't know why though... |
| 6: Cu | me either |
| 7: Ja | oh well |

Discussion

Comprehension processes are error-prone because they are constructive and approximate. Learners need to be error sensitive to attain error-proof comprehension. In this study, we examined the role of collaboration in improving comprehension monitoring and regulation in a distance communication situation, a matter that had not been investigated before. With a relatively well-controlled collaboration experiment, we first showed that distance collaboration is more beneficial to learning than working alone. In addition, performance in detecting contradictory information is also somewhat better in collaboration. Therefore, the better learning that occurred in the e-Pairs may be attributed to the process of collaboration.

Furthermore, to examine the role of collaboration in comprehension monitoring and regulation in detail, 3 good e-Pairs and 3 poor e-Pairs were examined. The good e-Pairs were not significantly better than the poor e-Pairs in comprehension monitoring (error detection). However, the regulative interaction quality of good e-Pairs' interactions was generally higher than that of poor e-Pairs. In general,

the good e-Pairs interaction quality was around the explanation level, whereas the poor e-Pairs interaction quality was between just checking answer and rephrasing.

Another interesting finding was from the comparison when both the good e-Pairs and the poor e-Pairs had successful monitoring. The poor pairs' regulative interactions were not highly activated even though their comprehension problems were monitored explicitly, while the good groups tended to indulge in higher level of regulative interaction.

Therefore, the results can be interpreted as supporting the claim that participants in distance collaboration benefit from collaborative interaction by improving their detection of comprehension failures, and implementing repair processes through regulative interaction. Also, the results support the research model that states that when comprehension failures or cognitive conflicts happen they should be detected and repaired to achieve correct comprehension or learning.

Thus, the model explains why some research on cognitive conflict finds increased learning while other research does not. As the model states, cognitive conflicts do not necessarily result in learning unless the conflicts are detected and resolved. In this experiment, no case was found to reach a cognitive resolution coded as negotiation. Instead, a lot of cases ended up with social negotiation. Here social negotiation means that conversants agree to blur their conflicts without reaching a clear resolution, as seen in the example conversation from the good e-Pair. Interestingly, there was also no instance of flaming, which is frequently reported in distance collaboration studies.

The so-called 'checking mechanism' (Miyake, 1986) may be a key for suppressing self-confirmation bias that may be dominant in solo learning. Self-confirmation bias is a tendency to stick to an already held explanation rather than developing alternative explanations. This tendency, when learning alone, tends to block learners from changing their representation by suppressing (Otero & Kintsch, 1992) and/or ignoring (Chinn & Brewer, 1993) inconsistent information that does not match with their representations. However, the confirmation bias in a group may be smaller, because groups are better than individuals at rejecting presuppositions (Gorman, Gorman, Latta & Cunningham, 1984), so long as they entertain hypotheses and alternative ideas, and consider justifications (Okada & Simon, 1997).

The results of this research are consistent with other research in the collaboration community. For example, Brown and Campione (1986) argued that "understanding is more likely to occur when a student is required to explain, elaborate, or defend his or her position to others; the burden of explanation is often the push needed to make him or her evaluate, integrate, and elaborate knowledge in new ways" (p. 1060). Also, Forman and Cazden (1994) identified *parallel*, *associative*, and *cooperative* interaction patterns, of which *cooperative* is the highest level – characterized as constantly monitoring, guiding and correcting each other's

work. Additionally, Barron (2000) argued that after contrasting a high-achievement group with a low-achievement group, greater monitoring for coordination between members would result in higher results. Therefore, collaboration might be an ideal way to improve individuals' monitoring and regulation abilities.

Finally, some aspects of this study should be noted that may limit generalizations of the results. One is that this experiment was highly controlled compared to other face-to-face collaboration research. We tried to separate the collaboration period from individuals' comprehension monitoring decision periods, to examine the effect of collaboration on individual learners' comprehension. Also, we tried to remove socially confounding variables. For example, the participants in each pair did not interact before the main tasks. Although this may appear to limit the ecological validity of this study in terms of face-to-face collaboration, it seems acceptable in terms of *e-ecological validity* since distance collaboration is often between anonymous individuals. Also it may provide a cleaner demonstration of the cognitive effects of collaboration on learning.

Second Order Isomorphism: A Reinterpretation and Its Implications in Brain and Cognitive Sciences

Abstract

Shepard and Chipman's second order isomorphism describes how the brain may represent the relations in the world. However, a common interpretation of the theory can cause difficulties. The problem originates from the static nature of representations. In an alternative interpretation, I propose that we assign an *active* role to the internal representations and relations. It turns out that a collection of such active units can perform analogical tasks. The new interpretation is supported by the existence of neural circuits that may be implementing such a function. Within this framework, perception, cognition, and motor function can be understood under a unifying principle of analogy.

Introduction

One of the central tenets in neuroscience is that neurons receive incoming spikes, process that spatial or temporal information, and then pass on the transformed information for further analysis. Also, neurons that fire together develop strong connections (Bliss and Collingridge 1993). Thus, the neurons represent features in the input, and connections encode relational context among features. This viewpoint is analogous to the second order isomorphism by Shepard and Chipman (1970; below, just S&C). However, a problem can arise depending on how we interpret S&C's theory.

The difficulty comes from the *static* role assigned to representations. In this paper, the representations and the relations are given an active role. When working as a collection, these active units can perform an analogical function. In fact, a similar active approach has been employed in previous work, resulting in the emergence of analogical (Hofstadter 1985; Mitchell 2001) or metaphorical (Narayanan 1999) functionality.¹ An important observation advanced in this paper is that the function of active representations and relations are very similar to that of neurons, and specific circuits in the cortex and the thalamus can actually *implement* analogical functions. Analogy is commonly attributed to higher cognitive faculties only, but it does not always have to be the case (Chalmers et al. 1992); it may be part of a larger set of human brain function including perception and motor function. I will discuss in the end how such an

¹Analogy and metaphor are closely related in that they refer to similarities in relations and attributes although the relative degree in each may differ (Gentner 1989).

Figure 1: S&C's Second Order Isomorphism. There are two objects, one square and one round in the world (on the left). The internal representations in the brain of these two objects are shown on the right. The vertical arrows represent the relations between the objects. The two horizontal arrows represent mapping from the world to the brain which is initiated by sensory transduction. Note: The square and circle on the right (in the brain) are just there for the ease of reference. They can be removed without causing any change in content (this applies to the rest of the figures).

analogical framework can allow us to better understand the nature of cognition and brain function.

Common Interpretations

Under second order isomorphism the brain needs to find the relation between the (1) relations between external objects and (2) relations between internal representations (figure 1). S&C's theory seems to be more appropriate in modeling how our brain represents the world than Locke's Isomorphism (Edelman 1998, 1999). In physical terms, we can interpret the figure as follows: (1) relation in the world (W1; coincidences in sensory events) (2) arrows from world to brain (B1; sensory transduction), (3) representations in the brain (B2; afferent connections), and (4) relation in the brain (B3; lateral connections). Of these, let us focus on what is available in our brain (B1-B3). If we take for granted the information our sensory transducers tell us, we can drop B1 from our discussion and focus on just B2 and B3.

An implicit message in figure 1 is that two objects are represented, and some brain process then judges the relationship between the two (the open arrow). Making this point more explicit, we can illustrate S&C's theory as in figure 2a (the diamond box). We can see that a difficulty can arise in such an interpretation; something has to perform the comparison function, but this creates an ever increasing levels in a hierarchical way (i.e. higher areas

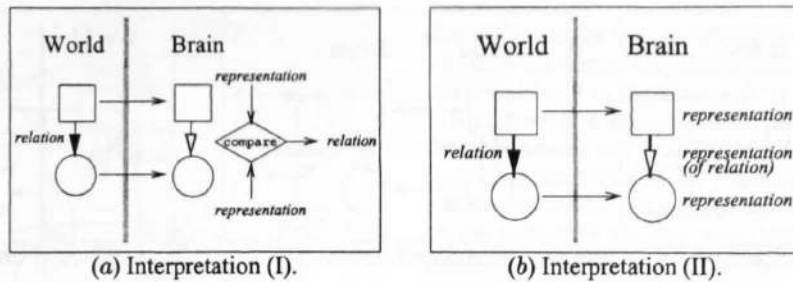

Figure 2: **Common Interpretations of Second Order Isomorphism.** (a) An explicit comparison mechanism is necessary to judge the relations between the two representations. (b) The comparison box is replaced by a representation of relation. However, this figure still requires a third-party to *evaluate* the representation of relation.

judging the output relation in the lower areas). However, as Hilgetag et al. (1996) noted, it is hard to determine a strict hierarchy among cortical maps (in this case, between visual areas). Also, as Zeki (2001) suggests, integration of these information may be a nonhierarchical process. Thus, representing something and delaying the interpretation until later may not work very well.

One can argue that the lateral connections *represent* the similarity relation, not requiring a separate interpreter (figure 2b). However, we still need something to evaluate (or interpret) the resulting representation. Thus, this reformulation just replaces the need for one kind of interpreter with another.

Assigning an Active Role to Relation

What can a relation be if it should not be a representation? The problem seem to come from representations and relations playing a *static* role. What if we assign an active role to the representations as shown in figure 3a? In the figure, I assigned an active role to the relation arrow itself, allowing one representation to invoke another. Thus the activation of the internal representation of the square *invokes* (or turns on) that of the circle, and vice versa.

Now consider how can we use this new active relation (note that it is *directional*) to describe the relations in the world. First, we have to know what kinds of relations exist in the world. There are two basic relations: spatial and temporal relations. Spatial relations are between objects, and they are causally bidirectional.² On the other hand, temporal relations are between events, and they are causally directional. When one event precedes the other, the reverse cannot happen simultaneously.

In the brain, action potentials only propagate in one direction along the axon, and the adaptation of synapses tend to learn causality (Song et al. 2000). Such connections are ideal for implementing temporal relations, but what about spatial relations? If we pair a unidirectional arrow from A to B with a reciprocal one from B to A, then we can indeed represent spatial relations with only directional arrows. If representations for object A and B simultaneously activate through mutual excitation, then

²Note that *causal* simply means that one event precedes the other in time.

they can represent the spatial relation between the two. So, let us update our figure again to include backward relational arrows (figure 3b). We can now think in terms of *temporal* relations only, because spatial relations seems to be a special case of temporal relations (at least in the brain).

The Role of Active Relations and its Neural Basis

In the previous section, I replaced the representation for relation by an active relation. What about the representations for the objects (or events)? Representation is an inherently static term (like a symbol), thus, we should take a more active viewpoint and ask *what action occurs* when a neuron detects a pattern in its incoming input, rather than focusing only on what a neuron represents. Knowing what representations *do* may be as important as knowing what they *stand for*.

To discover the relationship between things in the world, we need the motor capabilities as much as we need sensors. Thus, between the world and the brain there must be a backward arrow from the brain to the world. The resulting diagram is shown in figure 3c. This addition is crucial in learning the relations in the world (O'Regan and Noe 2001). The final diagram looks very similar to the basic circuitry in our brain. How can this final figure help us understand the mechanisms of the brain? The key is to understand what is the *action* taken by a neuron, no less than to know what it represents.

Active Relations: A Primitive for Analogical Processing

Now we have a single active functional unit: a neuron that fires a spike along the *active relational arrow* as soon as it detects a certain input feature. This unit alone cannot achieve much, neither can a serial chain of such units. The true power of this simple unit is revealed when it is used in a massively parallel way. This may be an obvious line of thought because that is what our brains seem to do. However, it turns out that the collective effort of these simple units can embody a simple yet powerful function of analogy.

We have to simplify matters to see how such neurons can process analogy. Let us assume there are six neurons in an imaginary creature's brain inhabiting the world

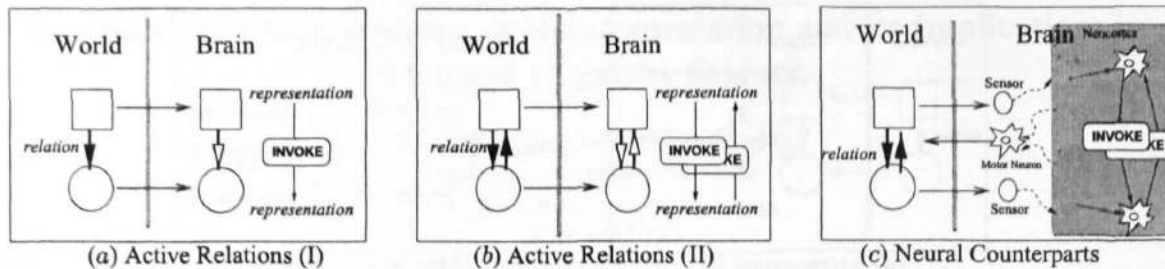

Figure 3: **A New Interpretation of Second Order Isomorphism.** (a) In this new interpretation of S&C's theory, an active role is assigned to the relation arrow. Notice that the INVOKE arrow is a single arrow, not one arrow going into and another leaving out of the box. Thus, the rounded box signifies that the arrow actually performs an *action*. (b) Backward relational arrows are added in the brain to account for the mutual, but directional nature of relations. With two relational arrows, both spatial and temporal relations can be implemented. (c) The neural counterparts of (b) are shown. The limiting term *representation* is removed, and the motor reaction (backward arrow from the brain to the world) is added. Sensory transducers are also explicitly shown.

of fruits (figure 4). After the fruit brain experiences the world of fruits, it will learn the co-occurrences between features and establish relational arrows as shown in the figure (arcs with arrows). Also suppose that the brain is partitioned into several specialized map areas (or partitions), as in cortical maps. Now suppose <apple>, <orange>, and <word-red> were presented to the creature simultaneously. If we track the activation, we can see that these detectors will turn on: apple detector, orange detector, color-red detector, color-orange detector, and finally, word-red detector. These activations are *input-driven*. Because the neurons are active, as soon as they detect what they are familiar with, they send out signals through the relational arrows horizontally across the cortex. As a result of this second order activation, the word-orange detector turns on, even without input. Now, here is the crucial moment. We can ask this question: *which neuron's firing was purely cortically-driven?* (note that we can view this as a filtering process). The result of the filtering is then <word-orange>. The significance of this observation is that this process is very similar to solving analogical problems. The input presented to the creature is basically an analogical query: <apple>:<orange> = <word-red>:<?>. The filtered cortical response <word-orange> can then be the *answer* to this query.³ Thus, active neurons can perform a rudimentary analogical function when the responses are filtered properly.

However, things can get complicated when combinations of objects are used as a query. Let us extend the creature's feature detectors to include concepts of small and big (not shown in the figure). Then we can allow the creature to learn the relations again. We can then present an analogical query like this: <big><apple>:<small><apple> = <big><orange>:<?>. In this case, if we follow the same steps as above we come across a problem. Because the answer we expect (i.e. <small> <orange>) already appeared in the query, if we look for purely

Figure 4: **World of Fruits.** A brain with object, color, and word detector neurons is shown. The six neurons each respond to these input features as labeled above. At the bottom is the fruit world, and the thick vertical arrows represent afferent input. The horizontal arcs are the relational arrows that point to their most frequently co-occurring counterparts that have been learned through experience. The gray vertical bars represent the partitioning of the brain into separate map areas (from the left to right, object map, color map, and word map). Note that for simplicity, the word-orange detector connects only to the color-orange detector, but not the orange detector, i.e. it is a word-color-orange detector, not a word-object-orange detector.

cortically-driven activations, the answer will be <word-red> <word-orange>. However, we can overcome this problem if we ask: *what are the most cortically-driven activities in each partition of the brain?* Because <big> and <apple> appeared in the input twice but <small> and <orange> appeared only once, the latter two can be selected, as well as the purely cortically driven activities listed above. Thus, even for derived activities that are input-driven, those that are less input-driven can survive and the correct analogical response can still be found among such activities that are more cortically-driven within each partition (or area). Note that <color-orange> also survives the filtering, but what is more important here is that a simple filtering process as described above can generate a *small subset of potential answers* to analogical queries. Although the simple analogical query presented above has a straight forward answer, in more complex analogical problems, there can be multiple answers depending on the interpretation (Hofstadter and Mitchell 1994; Mitchell 2001).

In this section, I have shown that active neurons that detect input features and establish relational contexts can collectively perform a rudimentary analogical function.⁴

³There is an issue of how the presence of <word-red> can affect the outcome at all. This problem will be discussed later in the discussion section.

⁴Analogical tasks can become much more complex than the ones shown here. The example in this paper is decidedly simple

Figure 5: Analogical Filtering in the Thalamus. The diagram shows a simplified thalamo-cortical loop that can perform analogical completion and selection and then propagate the selection back to the cortex. All connections shown are based on known anatomy of the thalamus and the cortex (Mumford 1995). I1 and I2 are input fibers, T1 and T2 are thalamic relay cells, and R1 and R2 are inhibitory nRt cells. C1, C2, C3, and C4 are cortical neurons (each is a set of neurons ranging multiple layers in a single cortical column). The neurons are either excitatory (+) or inhibitory (-), and the arrows are axons (pointing in the direction of action potential propagation). The numbered labels on each arc show the activity being carried. Black solid arrows are ascending fibers to the cortex and the cortico-cortical connections (relational arrows), and gray solid arrows are cortico-thalamic feedback. Black dashed arrows are inhibitory connections. The diagram shows a scenario when an input was presented to C1, which excites C2, and in turn generates the feedback from C2 to T2, which is then retransmitted to the cortex as a new query (ascending thick black arrow). The selection decision for further propagation to the cortex depends on the relative excitation and inhibition T1(T2) receive from C1(C2) and R1(R2). On the right of C2 (dotted) in the cortex is the subsequent cascade of analogical completions. Note that to avoid clutter, reciprocal connections in the cortex are not shown.

But does the brain function in such a way? In fact, an exact circuit that may be implementing such a function exists in the brain.

Neural Basis of Analogical Completion and Filtering

Two basic mechanisms are needed to account for the proposed analogical function: completion and filtering. Below, I will discuss how the cortico-cortical connections and the thalamo-cortical loop can implement these two mechanisms.

Completions may be accomplished by the long-range cortico-cortical connections (Mumford 1992). As mentioned earlier, synapses are strengthened when the presynaptic activity precede postsynaptic activity (Song et al. 2000), thus the connections can implement causal relations. Also, specific patterns of connections observed in animals (e.g. visual cortex of monkeys; Blasdel 1992) show how such patterns can implement specific completion functions. Computational models also showed

to clearly illustrate the basic mechanism.

how such patterns can encode feature co-occurrence and how they can dictate the performance of the model (Choe 2001; Geisler et al. 2001).

For filtering, a separate mechanism is necessary. In the thalamo-cortical loop, there exists a massive feedback from the cortex to the thalamus and an inhibition mechanism within the nucleus reticularis thalami (nRt) on the surface of the thalamus (Mumford 1995). This particular architecture has been thought to be involved in the analysis and synthesis of new memories (MacKay 1956), active blackboard (Harth et al. 1987; Mumford 1995), global workspace (Newman et al. 1997), and finally, generating attention and consciousness (Crick and Koch 1990). It turns out that these feedforward and feedback connections from nRt to the cortex together with the nRt inhibitions can filter the feedback from the cortex to promote the most cortically-driven feedback, i.e. the analogical answers. Let us first see how the purely cortically-driven activities are selected (figure 5). In the thalamus, ascending fibers (T1 to C1) branch out and excite the inhibitory nRt neuron R1 (T1 to R1). When the feedback from C1 to T1 comes back, it branches and stimulates R1. As a result, if the descending feedback had a matching ascending signal, the inhibition T1 receives is twice as high as other neurons in the thalamus that are activated by purely cortically-driven feedback (i.e. that of T2). If the synaptic weights are appropriate (i.e. $w_{TC} = 2$ and $w_{TR} = 1$)⁵, at T1 the feedback will cancel out, but at T2 the feedback will survive the inhibition and be retransmitted to the cortex (the *new query* arrow). Such a surviving cortical feedback, together with the input stimulus at the next moment form a new analogical query to the cortex, and the same process is repeated. That is, C2 elicits activities in C3, and in turn C4 through the thalamo-cortical loop (note that they can be quite far away). For the selection of the *most cortically driven* feedback, the mutual inhibitions in the nRt layer (e.g. between R1 and R2) may disinhibit (inhibiting an inhibitory neuron results in less net inhibition at the target; figure 5) each other and allow the more cortically driven feedback to go back to the cortex, even when all current cortical activities are input driven.

Discussion

The neural mechanisms described in this paper can only account for simple kinds of analogies, and in some case it can even seem as simple pattern completion. For example, $\langle \text{orange} \rangle = ?$ will result in the same answer $\langle \text{word-orange} \rangle$ as in the *Active Relations...* section. How can the term $\langle \text{word-red} \rangle$ in the original query affect the outcome at all? For this, I believe that among many possible completions, the general map area (i.e. the partitions in figure 4) that are activated by input gets higher preference. In this example, the fruit-map, word-map and color-map will turn on, thus purely cortical activations in other general maps (say odor-map, etc.) will not be as salient as that of $\langle \text{word-orange} \rangle$. Thus, in this

⁵Here, w_{YX} is the synaptic connection strength from neuron X to neuron Y.

way, the presence of <word-red> can indeed affect the outcome of the analogical query. A more precise neural mechanism for this kind of selection among areas (or maps) needs to be investigated further.

Researchers regard the analogical capability as the crux of high-level cognition (see Gentner et al. 2001 for a collection of current work on analogy). However, analogy does not need to be limited to high-level cognition. Recent results suggest that analogy may be needed in perception as well (Morrison 1998), and such an ability emerging in perceptual systems may even be a crucial requirement for cognitive development (Chalmers et al. 1992). Then it is not unthinkable that motor function also employ analogy in a similar manner (cf. sensory motor contingency theory by O'Regan and Noe 2001), thus we can then start to understand perception, cognition, and motor function under the unifying framework of analogy.

How can such a diverse functionality be integrated under a single framework of analogical processing? Massive connections exist within and across different functional areas in the brain, and the sensory/motor maps are topologically organized, i.e. nearby neurons are responsive to nearby features in the sensory space (Kohonen 1982; von der Malsburg 1973). Within each map, the feature detectors and the cortico-cortical connections learn to encode the relations (Choe 2001). It is possible that cognitive maps also have a topological organization where nearby areas learn to encode similar concepts, such as semantic maps or episodic memory maps (Miikkulainen 1993). When the sensory, cognitive, and motor maps are connected in an orderly way preserving their local topology, analogies can be drawn within and (more importantly) across different functional domains.

Within this huge number of maps specializing in different tasks, a cascade of multiple analogical completions can be going on in parallel, synchronized at each moment by the 40Hz rhythm to hold an instantaneously coherent state (Gray 1999; Mumford 1995). Such a state can then pose as another analogical query, and the process can repeat. When the cascade reaches a motor area, behavior will be generated. Memory content may also enter the analogical cascade, and this quasi-static contribution can prevent the continuously changing input stream from causing random cascades, thereby maintaining a more goal-directed and stable behavior. Specific mechanisms of how the memory content enters the thalamo-cortical loop, and how analogies are archived in long-term memory should be studied further.

Neuroscience research has revealed a lot about perception and motor abilities in the brain, but understanding the cognitive faculty still remains elusive. Investigation into cognitive functions can proceed under the analogical framework, where we can infer the functionality of the higher areas by backtracking the connections to the perceptual and motor areas and study their topology and analogical links. Specific predictions regarding the layout of the higher centers may be made based on the topology of the lower centers and the connection structure between the two, and experiments can then focus on verifying

these predictions. For example, there are orientation maps with smoothly changing orientation preference in V1 (primary visual cortex; Blasdel 1992), and there are object maps in TE (temporal area E; Tanaka 1996) that also change smoothly (for example, rotation of a head). The analogical framework predicts that there will be an orderly mapping from V1 to TE that preserve such local topology across different representation spaces.⁶ Similar mappings may exist between sensory and cognitive areas, and if such a mapping is found, we can start to understand the abstract cognitive functions based on concrete perceptual architecture.

The strong connection made in this paper between analogical function and specific neural circuitry can help us better understand both. The functionality of the target area of a neuron can be studied to understand *what action occurs* when a neuron detects a certain feature in the input. Such a study can reveal the kinds of relations implemented in the brain, thus providing us with insights into what kinds of analogies are possible. The mechanisms of neural circuits can also be further revealed by carefully designed analogical tests in perception, cognition, and motor function, and also in a combination of these different domains. Different types of unimodal and cross-modal analogical tasks can reveal how the different cortical areas are related and how they invoke each other. In studying such mappings across tasks and modalities, understanding the co-occurrence statistics of natural signals becomes increasingly important as they may give us a hint on how the connections are organized in the brain (Choe 2001; Simoncelli and Olshausen 2001).

Conclusion

In this paper, I analysed the difficulties that the common interpretations of S&C's second order isomorphism can cause in understanding the brain. I proposed an *active* role for representations and relations, and it turned out that collectively they can perform an *analogical function*. An important connection between analogical function and a specific brain circuit was then established, providing support for the new interpretation. This new viewpoint allows us to understand perception, cognition, and motor function under a unifying framework of analogy, and it can help us take a more focused approach in brain and cognitive sciences.

Abstract

Short-term performance data from a complex computerized cognitive test called SYNWORK1 were examined for age differences in transitory performance fluctuations in samples of 55 older and 57 younger adults. Profile analysis indicated that the older adults' performance trajectories were essentially parallel to those of the younger adults', but with the older adults performing at a consistently lower level on all four subtasks of SYNWORK1. These apparent age differences in level of performance were reduced substantially when a simple graphical approach was used to examine the performance trajectories. These results extend our knowledge concerning the nature of intraindividual variability while illustrating again some of the methodological inadequacies inherent in research comparing age differences in levels of cognitive performance when common statistical assumptions are even mildly violated. The competence of older adults can be underestimated based on a single measure of a group mean, thus leading to further risk of missing important learning strengths of older adults.

Selection and selection effects have received a considerable amount of attention from behavioral scientists (Nesselroade, 1988; Nesselroade & Thompson, 1995) and still remain one of the obstacles researchers must somehow overcome. The primary concerns, however, revolve around selecting a representative sample of participants from the population of interest (e.g. Cronbach, Gleser, Nanda & Rajaratnam, 1972) and valid indicators to represent the underlying construct under study (e.g. Little, Linderberger & Nesselroade, 1999). These, of course, capture only two of the ten possible dimensions defining empirical data in Cattell's data box (Cattell, 1966; Little et al., 1999), namely, the persons and variables dimensions, among other possible design configurations. Another relatively familiar dimension of the data box, occasions of measurement, has also been discussed rather extensively, especially in comparing the relative merits of cross-sectional versus longitudinal research design (e.g. Kraemer, Yesavage, Taylor & Kupfer, 2000). Another kind of selection effect that is inherent in almost any research designs, but has rarely been addressed, is the effect of averaging data across participants or oc-

casions of measurement. In a recently published article, Newell, Liu and Mayer-Kress (2001) question the common practice of averaging data across participants or occasions, presumably to remove the transient, noise-like changes from trial-to-trial, or during the "warm-up" phase at the beginning of a practice session, with the goal of singling out a global learning trend that is characteristic of all the participants across all the trials. As suggested by Lamiell (1981), both idiographic and nomothetic approaches have their own merits in answering certain research questions. However, when a group mean is used as the only index of a group's performance, the end of searching for a global trend in learning does not always justify the means of levelling out the individual differences in this aspect.

Idiographic and Nomothetic Approaches to Modeling Change

Over the past few decades, the importance of an idiographic approach (Allport, 1937; Murray, 1938) to studying human behavior has gained increased recognition. Considerable efforts have been devoted to integrate idiographic and nomothetic approaches in psychological research, thus allowing researchers to capture both the intraindividual variability, and the interindividual differences in various aspects of human behavior (Baltes & Nesselroade, 1979). Repeated assessments of the same individual often yield information on intraindividual variability in aspects thought to be relatively stable over short time-span, such as cognitive abilities and intelligence (see e.g., Horn, 1972; May, Hasher & Stoltzfus, 1993; Stigler, 1994), personality styles and other belief systems (e.g., Shoda, Mischel & Wright, 1994; Kim, Nesselroade & Featherman, 1996), as well as other more transient state-like fluctuations in affective states (e.g., Larsen, 1987; Shifren, Hooker, Wood & Nesselroade, 1997; Mumma 2001).

While many researchers are moving away from performing means comparisons at the aggregate level, the idea of taking a group mean as the unbiased estimator of the group, as well as the population that it represents, is so deeply entrenched in contemporary data analytic techniques that a majority of the between-group comparisons essentially

involve means. Although it is a well-known fact that other measures of central tendency, such as the median, might be a better estimator of a group's performance when certain statistical criteria are not met, or when there are outliers in the data that could potentially skew the results of one's analysis, most of the available statistical tests, such as ANOVA, are based on means comparisons. Even in cases where intraindividual variability is modeled explicitly, such as in growth curve analysis (McArdle & Epstein, 1987; Francis, Fletcher, Stuebing, Davidson & Thompson, 1991; Meridith & Tisak, 1990), conclusions on intraindividual changes in levels of performance still derive primarily from means. Adding to these methodological difficulties of capturing representative idiographic information, of course, are the conceptual difficulties of summarizing the interindividual differences in a way that is helpful for making empirical decisions. A graphical approach is a useful supplement to other more rigorous statistical approaches, as it helps to depict a summary picture of both the intraindividual and interindividual aspects of change.

Transitory Changes in Cognitive Performance as Meaningful Intraindividual Changes

Despite increased awareness of the limitations of using an aggregate measure to represent a group, the same limitations that exist when applied to individual data were not addressed as often. Just as a group mean does not necessarily represent the group as a whole, an individual's mean score is limited in its own way. The transient fluctuations observed during the initial phases of an individual's learning history should not unthinkingly be regarded as "outliers" that ought to be levelled out. Unfortunately, most experimental studies aimed at capturing deterministic dynamics in transitory learning fluctuations as observed during the "warm-up" phase are limited to studies in the area of motor development (e.g. Adams, 1961; Schmidt, 1982; Thelen, 1994). Individuals' cognitive learning curves as reported by some researchers (e.g. Salthouse, Hambrick, Lukas & Dell, 1996) do in general resemble the learning curve of motor skills. However, very few studies have focused on examining the patterns of transitory changes in human cognitive performance and even fewer studies emphasize learning as an ongoing refinement of errors in the face of external perturbations.

Objectives of This Study

In this paper, we examine transitory changes in individuals' short-term adaptive responses and compare these responses among adults of different ages. We also demonstrate some of the inadequacies inherent in comparing adults of different ages on the basis of

their group means when common statistical assumptions are even mildly violated. Finally, we present a simple graphical approach that serves as a supplement to means comparisons at a group level, and an alternative to summarizing changes at an individual level.

Method

Participants

This sample consisted of 55 older adults (36 female and 19 male), and 57 younger adults (38 female and 19 male). The older adults' ages ranged from 60 to 93 years ($M = 73.73$, $SD = 7.26$), and the younger adults' from 17 to 28 years ($M = 19.18$, $SD = 1.75$). The younger adults were recruited from the undergraduate participant pool in a southeastern university and were rewarded with course credits for participation in this study. The older adults were recruited from the Charlottesville community through newspaper advertisements and direct solicitation at senior centers. Both age groups rated themselves as in reasonably good health, with self-ratings of health averaged between average to good (on a 4-point scale from 1—excellent to 4—poor, $M = 2.27$ and $SD = 1.00$ for older adults; $M = 1.91$ and $SD = 0.87$ for younger adults).

Materials

The cognitive performance of the participants was assessed using a computer program called SYNWORK1. The SYNWORK1 program is a computerized multi-tasking test environment designed by Elmsore (1994) to examine an individual's ability to perform multiple tasks concurrently. Figure 1 shows the four primary tasks that are measured on SYNWORK1, including a memory task, a self-paced arithmetic task that involves using mouse-click to manipulate the plus and minus panels to adjust the sum from four zeros (0000) into the correct sum of two given numbers, a visual monitoring task, and an auditory discrimination task. Points are given for correct responses and taken away when a task is neglected or performed incorrectly. An individual's total score is constantly updated and is shown in the middle of the four task quadrants.

Procedure

Due to the complexity of the SYNWORK1 program, the participants were first given a short training session during which they practiced the four SYNWORK1 tasks one at a time, followed by a one-minute session during which they practiced the four tasks simultaneously. After the participants were told to strive for their best possible scores, we began recording their performance data on SYNWORK1 over nine consecutive trials, with each trial lasting about one minute.

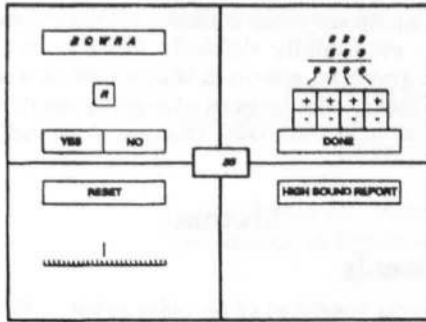

Figure 1: The SYNWORK1 program designed by Elsmore (1994) to test human synthetic work performance

To induce some short-term transitory fluctuations in the participants' performance, we manipulated the difficulty levels of the SYNWORK1 program throughout the nine trials by speeding up or slowing down the timing at which each task appeared. During the more difficult sessions, we also increased the number of addends for the arithmetic task, and the number of target letters the participants had to remember for the memory task. This sudden increase in the difficulty levels of the four tasks was expected to induce a small amount of perturbations in the individuals' responses and the individuals' ability to adapt to these sudden perturbations was taken as an indication of their adaptive behavioral patterns. During a particular trial, the SYNWORK1 program was governed by one of three possible sets of parameters we classified as easy, mid-difficulty, and difficult. The participants were exposed to one of two sequences of altering difficulty levels in the order of {M, E, M, D, M, E, M, D, M}, or {M, D, M, E, M, D, M, E, M}, where M represents mid-difficulty, E represents easy, and D represents difficult sessions. The total number of correct memory, arithmetic, visual, and auditory responses for each of the nine trials were used as the primary dependent variables in this study to determine if the two age groups had different performance profiles on each of the tasks.

Results

Prior to analysis, the participants' task scores over nine trials were screened for outliers and departure from other statistical assumptions. Several outliers were detected among younger adults who performed too poorly on the memory task, older adults who performed too well on the arithmetic task and the visual task, and among younger adults on the auditory task due to the restricted range of scores observed in that age group. These outliers were retained in subsequent data analysis as they were thought to reflect reasonable range of fluctuations in performance. No missing values were observed in the data. When

subject to a MANOVA test, the task scores of individuals exposed to the two sequences of difficulty levels were not statistically different from each other. After confirming that, a profile analysis was used to evaluate the differences in level, parallelism, and flatness of the two groups' responses on the four tasks, with age group as the independent variable.

Profile Analysis

The descriptive statistics of the two age groups are presented in Table 1. Consistent with findings reported in the aging literature, the younger adults were found to perform at a significantly higher level on the memory task, $F(1,110) = 132.17, p < .001$; the arithmetic task, $F(1,110) = 223.69, p < .001$, and the auditory task, $F(1,110) = 106.56, p < .001$, as determined by using Wilk's criterion. The visual task was the only task that did not show significant difference in levels between the two age groups.

Table 1: Descriptive Statistics of the Older and Younger Adults.

	Mean		Standard Deviation	
	Old	Young	Old	Young
Memory	5.77	9.47	2.92	2.20
Arithmetic	0.21	1.84	0.60	1.45
Visual	70.80	72.22	22.51	21.49
Auditory	0.81	1.78	0.83	0.76

When averaged across groups, scores on all four tasks were found to deviate significantly from flatness by Hotelling's criterion on all four SYNWORK1 tasks ($p < .01$ for all). This simply confirmed that the experimentally imposed perturbations did lead to some fluctuations in the participants' performance. There might also be some learning taking place, as shown by the slight increase in means over the nine trials. Using Wilk's criterion, however, the older and younger adults' profiles were not found to deviate significantly from parallelism, except on the arithmetic task, $F(8, 103) = 2.98, p = .005$. The arithmetic task might be too cognitively demanding for the older adults, thus causing them to avoid the task altogether. Aside from this, the two age groups did not react to the experimental perturbations in a statistically different way over the nine trials.

Graphical Representation of Intraindividual Variability

The conceptual difficulties of summarizing information at an individual level can be illustrated using Figure 2, in which all the individuals' total scores on

Figure 2: The total scores of all the individuals in the sample.

SYNWORK1 are shown over the nine trials. Different individuals have their own distinct trajectories, making it hard to summarize the performance of the group as a whole. The conventional means plot (see Figure 3) may be helpful in providing a summary picture, but could also mask important information in the data. To further examine the performance of the two age groups as captured by other descriptive measures, the 10th, 50th and 90th percentiles of the two groups' scores on the four tasks were plotted and compared using S-Plus' Hmisc library (Harrell & Alzola, 2001). Due to space limitations, we chose to include only the means and percentiles plots for the memory and auditory tasks here.

As shown in the plots in Figure 4, the age differences in performance levels reduced substantially when the percentiles plots were used to represent the performance of the two age groups¹. When compared to adults from the same age group, older adults who performed at the 90th percentiles on the memory and arithmetic tasks (omitted here) were found to show performance that closely resembled younger adults whose scores were near the median levels of their peers². Older adults in this category were observed to make more marked improvements on the memory and arithmetic tasks toward the end of the experiment. A similar pattern was observed on the auditory task, except that the relatively well performing older adults (i.e., the 90th percentile group), started out with performance trajectory that was identical to the trajectory of younger adults who performed at the median level, but after the 7th trial, caught up to the performance of younger adults who performed at the 90th percentile level and performed at exactly the same optimal level after the 7th trial. The younger adults who performed

¹We also plotted the trajectories of younger and older adults at less extreme percentile levels (e.g. 25th and 75th percentiles). A similar, but smaller magnitude of reduction in age differences was observed.

²The percentile levels were calculated separately for each task and each age group.

Figure 3: The means and the 95% confidence limits of the older and younger adults' scores on the memory and auditory tasks.

at the 90th percentile levels were performing at the optimal level on the memory, visual and auditory tasks very early on, achieving the maximum possible scores during almost all of the trials. Their only source of improvement in scores derived primarily from the self-paced arithmetic task, on which their scores continued to improve throughout the course of this experiment. On the other hand, older adults at the 90th percentile level were observed to have rather uniform improvements on all four tasks, and more trials were required before they could attain the same level of performance the well performing younger adults could achieve at an early phase.

Another important source of variability constituted by age stemmed from the lack of clear improvements observed among older adults who performed at the 10th percentile level. The relatively poor performing younger adults (those at the 10th percentile level) were able to capitalize on the memory task and auditory task as time progressed much better than older adults of comparable performance level. Nevertheless, older adults at the 10th percentile level did demonstrate their own learning strengths on the visual task—they attained a considerable amount of improvement on the visual task from trial one to trial two, and maintained a rather persistent level of performance before a sharp decrement in scores was observed during and after the 8th trial, presumably due to fatigue and decreased attention span. When the

Figure 4: The 10th, 50th and 90th deciles of the older and younger adults' memory and auditory scores.

plots of individuals from less extreme percentile levels (e.g. 25th and 75th percentiles) were examined, similar fluctuation patterns that differed slightly in levels were observed, revealing interesting individual differences in performance fluctuations within, as well as between different age groups.

Discussion

In this study, SYNWORK1 was used as an active interface for capturing the age differences in performance fluctuations when individuals were faced with ongoing external perturbations. As Jones and Conrad's (1933) quotation of Thorndike's remark put it, "...individual differences amongst those of the same age...enormously outweigh differences between ages" (p. 258-59). The common approach of comparing age differences in levels of cognitive performance by using group means inevitably under-represents the complexity underlying the variability in performance both within and between different age groups, especially when the two age groups have unequal variances in many respects. Due to the lack of a clear definition of what constitutes a normative representation of the older adults population, the issue of identifying and eliminating outliers becomes tricky. Results from our profile analysis showed findings that were consistent with those reported in the literature (e.g. Erber, 1976). Essentially, adults of different age groups were found to exhibit simi-

lar, significant improvements on cognitive or intelligence tests as practice effects accumulated, but the younger adults' level of performance was almost always higher than the older adults' on all the measurement occasions.

Using group means and the changes in means as the sole indicators of the performance of these older and younger adults might be informative in its own way, as demonstrated by the profile analysis in this study, but fails to acknowledge the differences in performance profiles among individuals of the same age group. In fact, the younger adults in this study, who were all recruited from the same university and were often thought of as representing a rather homogeneous group, showed different dynamics in their performance fluctuations when the trajectories of individuals from different percentiles were compared. The trajectories plotted using the percentiles of the younger and older adults also revealed very consistent patterns in performance fluctuations that reflected our experimentally imposed alterations in task difficulty levels very accurately. More importantly, the age differences in levels of performance were reduced substantially when the percentile scores of these two age groups were examined, revealing some of the older adults' unique strengths in learning that started surfacing at a relatively more gradual pace than for the younger adults.

Of course, younger adults of the higher ability group might be encountering ceiling effects on those tasks from a very early phase. In addition, with the data from the present study, there is no way for us to determine whether the high-performance younger adults will resemble the high-performance older adults in any way when they get older. However, by using a simple graphical approach, we presented some of the inadequacies of using group means as the only representation of the dynamics of the group as a whole because a researcher may risk bypassing some of the interesting dynamics within the group by not looking at the results offered by other alternative methods.

Reminiscence and Arousal: A Connectionist Model

Eric Chown (echown@bowdoin.edu)

Department of Computer Science, 8650 College Station
Brunswick, ME 04011 USA

Abstract

In recall tasks, increased levels of arousal soon after presentation time leads to short-term performance that is contradictory to standard memory models. Despite the fact that long-term recall is excellent in such situations, short-term recall is poor, worse than in the long-term case. This article presents a model, based upon Hebb's cell assembly construct, to account for this puzzling data. The system, called MultiTrace, has previously been used to model a lexical priming task and was adapted with only minor changes for this task.

Introduction

The relationship between arousal and short-term memory has presented a problem for standard memory models for nearly 40 years. In a pair of studies in the early 1960s Kleinsmith and Kaplan (1963; 1964) found that while there is a positive correlation between increases in arousal and long-term memory, in the short-term case the reverse is true. Further, in cases of where arousal markedly increases, short-term recall is substantially worse than long-term recall, an effect called "reminiscence." Because these results challenge standard memory models in which short-term memory is necessarily stronger than long-term memory, they have often been criticized, but just as often have been replicated (Eysenck, 1977; Weingartner & Parker, 1984; Revelle & Loftus, 1990). To date, no widely accepted explanation has ever been provided to account for the data (see, for example, Revelle & Loftus, 1990). However, more modern views of memory, updated with an increased understanding of the underlying neural mechanisms involved, can now provide a plausible explanation of the data. This article presents an existing model that can account for the data in a way that is surprisingly close to the original account of Kleinsmith and Kaplan.

The model used in this article, called MultiTrace (Sonntag, 1991; Chown, 1994; Forbell & Chown, 2000), is a variant on the cell assembly construct proposed by Hebb (1949) and later extended by Kaplan, et. al. in their TRACE system (1991). What makes the cell assembly model so attractive for this task is that, unlike many other neural network models, cell assemblies have complex temporal dynamics directly affected by the physiological properties of neurons. MultiTrace is an extension of the single cell assembly

TRACE model to allowing sequence learning through the inclusion of multiple cell assemblies.

This article will begin with a discussion of the Kleinsmith and Kaplan data and some of the theoretical problems it raises. Next the MultiTrace model is presented, highlighting parts of the model directly relevant to this task. Finally, the original experiments are modeled in MultiTrace and the results are compared to the originals.

Reminiscence

The learning paradigm used by Kleinsmith and Kaplan was a simple paired-associate task. In the first experiment, subjects were shown a word for four seconds and then the same word and a number for another four seconds. The recall task was to remember the number when the word was given as a cue. Changes in galvanic skin response (GSR) deflection were used as the measure of arousal response. These changes were sorted into "high" and "low" categories for each subject. In the long-term case (one week), Kleinsmith and Kaplan got the results that they expected – recall was better for words in the "high" category. The surprising result was that in the short-term cases (2 minutes and 20 minutes) this was not the case, and further, recall in the "high" categories was worse than in the long-term case. When the arousal deflection was "low", the recall curves generated were what would normally be predicted – short-term recall was very good but decayed over time (Figure 1). In the "high" case, however, Kleinsmith and Kaplan found that the recall curve was essentially an inverted U (Figure 1). To address criticism of the original study, Kleinsmith and Kaplan replicated their work the following year, but used nonsense syllables instead of words, and got qualitatively similar results.

Figure 1: The Kleinsmith and Kaplan data.

The major question raised by the Kleinsmith and Kaplan data is why recall is so poor in the short-term case in the high deflection condition. Among other things, the results would seem to discount the notion that long-term memory is just a decayed version of short-term memory, or that memories transition from short-term into long-term storage.

Kleinsmith and Kaplan proposed that the neural circuits involved in the task rapidly reverberated under conditions of increased arousal and were relatively unavailable because of that reverberation. They went on to theorize that this same reverberation was responsible for the better long-term recall due to greater perseverative consolidation. This explanation was discounted due largely to the lack of an accepted mechanism that could account for the unavailability of the circuits in the short-term. Kleinsmith and Kaplan proposed neural fatigue as the mechanism, but this is a property of neurons that only started to become accepted more than 20 years later (Ito, 1992; Artola & Singer, 1993) and was criticized at the time for being implausible.

Most of the alternative explanations proposed in the interim involved some combination of consolidation and interference in conjunction with separate short and long-term memory mechanisms. None of them were satisfactory (Revelle & Loftus, 1990), and work in the area appears to have died out due to the lack of attractive theories. The model presented here is closely related to Kleinsmith and Kaplan's original proposal. The neural circuits in this case are cell assemblies. In this paradigm learning comes as the result of correlated neural activity (this is usually called Hebbian learning). One effect of an increase in arousal is to generate intense and focused activity in the brain (Oades, 1985). In a Hebbian paradigm one byproduct of intense activity is that the areas of focused activity experience more correlated activity and therefore more learning. As this activity stretches out over a few seconds it essentially serves as the memory consolidation period. On the other hand, this intense activity also tends to fatigue the neurons that have been repeatedly firing. The net result is that these fatigued cell assemblies temporarily require an unusual amount of stimulation in order to become reactivated.

The MultiTrace Model

Hebb developed the cell assembly construct to address questions concerning the temporal nature of neural processing. Hebb needed a way to explain how neurons could hold information over time (e.g. the psychological concept of "set") even though they essentially pass through information. He solved this problem by proposing that cell assemblies consist of a large collection of neurons that are highly interconnected. These connections form a kind of loop

that enables the cell assembly to effectively hold information through the reverberation of the loop once it becomes active. In this way cell assemblies are neural analogs of "symbols." Hebb's theory was rejected after early models showed that the recurrent connections tended to lead to out of control activity (Rochester, et al., 1956). This was because Hebb had cautiously omitted inhibition from his model because no direct physiological evidence existed for it at the time. More recently, however, cell assembly theory has undergone something of a revival as experimental evidence for their existence has been found (Amit, 1995) and several models have been proposed that extend Hebb's original conception (Kaplan, et al, 1991; Hetherington & Shapiro, 1993; Amit, 1995; Horn, et al., 2000).

TRACE

MultiTrace is based upon one such model, the TRACE (Tracing Recurrent Activity in Cognitive Elements) model of Kaplan et al. (1991). TRACE is based on the idea that there must be counterbalancing forces to offset the tendency of cell assemblies to continually reverberate. The most important of these forces are *inhibition*, which provides a mechanism for selection and for competition with other cell assemblies, and *fatigue* which ensures that cell assemblies do not stay active indefinitely.

TRACE is modeled as a set of difference equations that capture the biological properties of the population of neurons that comprise the cell assembly. The equations are similar to population models used by biologists. Rather than trying to work out the interactions of neurons individually, the Kaplan group decided to work at a slightly higher level in order to understand their collective behavior. TRACE units, therefore, are more complex than typical neural network units, but are still at a higher level than neurons.

The crux of any cell assembly model is that activity in a cell assembly is the basis of cognitive processing. Perception, for example, would correspond to a cell assembly reaching some internal threshold of activity (defined as the percentage of active neurons at any given time step). TRACE added several theoretical constructs to Hebb's theory that are relevant to this article; they are inhibition, fatigue, and short-term connection strength.

Inhibition serves numerous roles in cognition, including selection and providing a mechanism for perceptual competition. These will be discussed in more detail in the discussion of the MultiTrace extension to TRACE.

Fatigue provides a kind of shut-off mechanism to cell assemblies, ensuring that the cognitive system does not literally get stuck on a single thought. It has also been

speculated that fatigue may play a central role in learning in much the same way that muscle fatigue is crucial to getting stronger. Neurons, like muscles are physical systems that require fuel (e.g. transmitter substances) to work efficiently. With extreme usage that fuel supply can run out and essentially damage the system. With muscles it is the repair of the damage that makes the muscle stronger. It may be that neural fatigue is a kind of signal to rewire synapses in order for the system to run more efficiently in the future.

The important function of short-term connection strength with regard to this article, is that it provides a mechanism for short-term memory. Short-term connection strength (STCS) is based on post-tetanic potentiation, the property of neurons that once they fire they are temporarily more likely to fire again. In other words, once a cell assembly has been active, for a short time it will be easily reactivated (or recalled). STCS's counterpart in TRACE is long-term connection strength (LTCS) which comprises the long-term structure of the brain and is what changes with learning.

The TRACE equations are shown in Table 1. As difference equations, they are updated on each time step (set at 10 milliseconds in TRACE).

Table 1: The TRACE equations

Update Equations	Delta Equations
$A(t+1) = A(t) + \Delta A$	$\Delta A = P - \bar{M}$
$F(t+1) = F(t) + \Delta F$	$P = (A + \bar{A}) \bar{I} \bar{A} V$
$S(t+1) = S(t) + \Delta S$	$M = (A^{\theta_i} + \bar{A}^{\theta_c}) \bar{V}$
$L(t+1) = L(t) + \Delta L$	$\Delta F = \phi_g A \bar{F} - \phi_d F$
	$\Delta S = \sigma_g A \bar{S} - \sigma_d S$
	$V = \frac{1}{v} (S + L) \bar{F} A_R$
	$I = I^{exc} - I^{inh}$ (see text)
θ_i : unit loss	A: activity
θ_c : inhibitory competition	F: neural fatigue
v : normal factor	S: STCS
ϕ_g : fatigue growth	L: LTCS
ϕ_d : fatigue decline	I: network input
σ_g : STCS growth	A_R : Arousal
σ_d : STCS decline	Equation Note: \bar{X} denotes quantity $(1 - X)$

MultiTrace

MultiTrace extends TRACE by putting TRACE units into a larger architecture consisting of multiple cell assemblies. In addition to the properties of the individual units that come from the TRACE model, units also have properties associated with the architecture of the brain. There are two properties that are important with regard to this article and they have

previously been used with MultiTrace to model a lexical priming task (Forbell & Chown, 2000). The first property is what Kinsbourne (1982) called "the functional distance principle." This is the property that similar concepts tend to interfere with each other more than dissimilar ones. In neural terms, similar concepts are processed near each other in the brain and will tend to inhibit each other. This provides a means for perceptual competition among other things. The second property is that cortex consists of a large number of layers. It is possible to think of these layers vertically, with the perceptual layer on the bottom and more abstract layers higher in the hierarchy. In the original TRACE paper it was proposed that each layer consists of cell assemblies with different temporal properties (in the context of the model this is achieved by varying the parameter settings).

Figure 2 is drawn from (Forbell & Chown, 2000) and demonstrates both of these properties. The lexical layer is more abstract than the phoneme layer and is therefore at a higher level in the cognitive hierarchy. In this case the lexical layer is one level up since words consist of sequences of phonemes. Each layer has slightly different properties (for example, perceptual layers will need to recover from fatigue very quickly so the perceptual system can always be ready for the next input) and similar items within a layer tend to compete with each other through lateral inhibition. In the figure, for example, "BLAST" will inhibit "BLACK" more than it will inhibit "BLUES" since it is more similar to "BLACK."

Figure 2: The two-tiered connectionist architecture. Similar words are processed near each other and will tend to inhibit each other based upon distance.

The main extensions to the original TRACE model added in MultiTrace is to use a more complex input function that combines several sources of inhibition as well as excitation. The input equations found here are the same as in (Forbell & Chown, 2000) and more details on the derivations can be found there.

For clarity a unit's input can be divided into inhibitory and excitatory components. Because of the functional distance principle, neighboring units will tend to inhibit each other. The amount of inhibition is a function of the distance between units and the activity and fatigue of the inhibiting unit:

$$I_{jk}^{inh} = \frac{A_j(1 - F_j)}{D_{jk}}$$

j: source unit
k: target unit
D: distance

There is an additional inhibitory factor in the model termed "regional inhibition" which is designed to limit the total activity in any given cognitive layer. Therefore the total inhibition for a unit, k, is the sum of the inhibition from other units, plus its regional inhibition:

$$I_k^{inh} = \frac{1}{L} \left(\sum_{j=1}^n I_{jk}^{inh} \right) + R \left(\sum_{i=1}^n A_i \right)$$

n: number of units in a layer
R: regional inhibition factor
L: lateral inhibition factor

Excitatory input is computed in a conventional connectionist manner. The only difference is that units have both long-term and short-term connections between them:

$$I_{jk}^{exc} = (LTCS_{jk} + STCS_{jk})A_j$$

$$I_k^{exc} = \sum_{j=1}^n I_{jk}^{exc}$$

j: source unit, k: target unit
n: number of incoming connections for unit k

Once the excitatory input is computed it is run through a standard sigmoid function to force it to values between 0 and 1.

Learning in MultiTrace is based upon the Hebbian learning rule that connections between units are increased when they fire nearly simultaneously. This is modulated by the fatigue (raised to the power P) of the unit as well as a learning rate, Λ .

$$\Delta LTCS_{kj} = \Lambda * A_k * A_j * F_k^P$$

Simulation and Results

The experiments simulated in this article are from (Kleinsmith & Kaplan, 1964). The only changes to MultiTrace from (Forbell & Chown, 2000) were in parameter settings related to operating at a different level of cognition than the perceptual experiments in that work. The parameters internal to units are largely based upon those in the original TRACE paper (Kaplan, et. al., 1991) since it was meant to model higher cognition. With regard to the experiments, the important parameters are the ones affecting fatigue, short-term connection strength and arousal. The values are shown in Table 2. With regard to arousal, the value shown is taken to be a baseline that varies experimentally as described below.

Table 2: Unit Parameters

Parameter	Description	Value
Φ_g	Fatigue Growth	0.007
Φ_d	Fatigue Decline	0.0001
σ_g	STCS Growth	0.1
σ_d	STCS Decline	0.001
A_r	Arousal	0.95

In terms of the architecture selected, a two-tiered system was used similar to the one shown in Figure 2. The reasoning is that nonsense syllables were selected specifically to be unlike normal words. This means there should be no perceptual competition between the nonsense syllables and the associated digits. Further, connections between the layers should be relatively uniform and weak. One difference between the layers is that nonsense syllables represent "unlearned" or weakly connected cell assemblies. Digits, on the other hand, are frequently used, and thus the cell assemblies that represent them should be tightly connected. In the original TRACE paper it was proposed that unlearned cell assemblies have an internal long-term connection strength (LTCS) of 0.2, while well-learned ones have an LTCS of 0.5. In the experiments that follow, this is the only difference between the two layers.

The basic format of a given run of a simulation is simple: a unit was randomly selected from the first layer and was stimulated. Meanwhile, a starting arousal level was also generated. Then two seconds later a random arousal deflection was generated. This was categorized as either "high" or "low" by comparing it against the median arousal level. Two seconds after that the original unit was again stimulated along with a randomly selected unit from the second layer. In the short-term case the network was then allowed to run for two minutes of simulated time. Then arousal was again set randomly (it was found that there was no correlation between arousal at presentation and arousal at recall

(Kaplan & Kaplan, 1970)) and the first unit was re-stimulated. If the second unit became active due to stimulation from the first, it was categorized as successful recall. The procedure was the same in the long-term case except that factors such as fatigue and STCS were simply reset to normal levels to simulate the passage of time. In addition, the network learned (in the form of changes in inter-unit LTCS) in the long-term, but not the short-term case. This is because consolidation data shows that the physical process of long-term memory generally takes at least 20 minutes (Miller & Marlin, 1984).

The 20-minute recall case was dropped for a variety of reasons. One reason is that the simulation essentially runs in real time. This means it is not possible to run a significant number of trials as compared to the 1000 trials in the other cases. A second reason is that the 20-minute case mixes short-term and long-term memory processes. There is no a priori way of knowing how much the recall rates at those times are due to either factor. The tested cases are purely short-term memory on the one hand, and purely long-term memory on the other, and therefore can generate more meaningful results. There is no obvious way to set the learning rate in the 20-minute case and trying to determine one experimentally would be extremely difficult due to the time-scale involved.

The architectural parameters relating specifically to MultiTrace are given in Table 3.

Table 3: MultiTrace Parameter Settings

Parameter	Description	Value
R	Regional Inhibition	0.1
L	Lateral Inhibition	3
Λ	Learning Rate	0.03
P	Fatigue Power	3

To test the robustness of the model, in each simulation run a new "subject" was generated by randomly perturbing all of the relevant model parameters. For example, if the parameter's ideal value was set at 0.1 a new one was generated for each run by using a Gaussian distribution with a mean of 0.1 and a standard deviation of 0.01. In all, 1000 runs were done for both the long and the short-term cases. The results are shown in Table 4.

Table 4: Recall Rates

Arousal	2-minute	1-week
Low	0.55	0.25
High	0.11	0.50

The results are similar to those obtained by Kleinsmith and Kaplan, though exact comparisons cannot be drawn since they published curves, but not the actual numbers. Further, pursuit of an exact match is probably a fruitless enterprise as the results were later reinterpreted with different scoring methodologies (Kaplan & Kaplan, 1970). The conclusion of that study was that the *trends* in the results were consistent across experiments and scoring, but with a fair degree of variation. The important trends being that initial recall is high in the low arousal case and then declines, and that the reverse is true in the high arousal case.

It is important to emphasize that the parameters for this work were drawn from previous sources. The TRACE parameters in Table 2 were taken directly, without modification, from an extension to TRACE where arousal was added (Chown, 1994). These parameters are different than those used in (Forbell & Chown, 2000) due to the fact that different levels of cognition were being modeled. In the previous case the individual units represented phonemes; in the current case the cell assemblies represent entire syllables. Since syllables are comprised of sequences of phonemes the time course of activity must be longer. In terms of the MultiTrace architectural parameters in Table 3, the only parameter that varied from (Forbell & Chown, 2000) was the learning rate. It is reasonable to believe that the learning rate for lexical material is different than the learning rate at higher levels of cognition, such as at the word level.

Discussion

This work serves two purposes. First, an existing biologically grounded model was used to address a theoretical problem in the memory and arousal literature. The results support Kleinsmith and Kaplan's theory that their data can be explained in terms of reverberating neural circuits. Second, their data provides further constraints in exploring the temporal dynamics of neural processing in cognition and the development of cell assembly-based models.

TRACE and MultiTrace were developed as modern versions of Hebb's cell assembly construct. The individual parts of each model were theoretically motivated as part of a general cognitive theory. The fact that MultiTrace was able to model the Kleinsmith and Kaplan results with only minor parameter changes lends credence to Kleinsmith and Kaplan's original supposition about the underlying cause of their results. In turn, their data, which has defied other explanations for four decades, shows that the physiology of the brain, including architectural factors such as wiring, are critical in fully understanding human learning.

Hebbian learning has become increasingly popular in connectionist models in recent years and the paradigm explored in this paper provides evidence of how it

might be useful in a general theory of learning. The postulate that learning comes as the result of correlated neural activity implies that variation in learning can largely be explained in terms of factors that impact that activity. Arousal is a primary example of such a factor. Cell assembly models such as MultiTrace have the potential to explore this idea by modeling the dynamics of neural activity at a fairly high level while still incorporating physiological constraints. These constraints are often architectural, depending on factors that are not easily modeled in many other types of neural networks where, for example, the temporal dynamics of the individual units are essentially irrelevant.

Dynamic models are gaining in popularity, and control issues, such as those involved in the TRACE and MultiTrace models, will be central in their continuing development. Time dependent data, such as the Kleinsmith and Kaplan data is crucial to the development of these models as it provides a source of constraints on how the models must operate. This work is part of an ongoing process of collecting such constraints and using them to develop and calibrate the model. The diversity of the tasks involved – e.g. modeling priming and interference effects in phoneme processing versus modeling paired-associate learning – is crucial in showing the generality and power of the model.

How Conceptual Metaphors are Productive of Spatial-Graphical Expressions

Timothy C. Clausner (Clausner@HRL.Com)

HRL Laboratories, LLC

Human Centered Systems Department, 3011 Malibu Canyon Road
Malibu, CA 90049 USA

Abstract

The theory of conceptual metaphors is adopted in which conceptual relations are productive of linguistic metaphorical expressions. Conceptual metaphors vary in their degree of productivity according to semantic principles. Spatial-graphical expressions of non-spatial concepts are investigated providing evidence that they are instantiations of metaphors. For three cases of differing productivity it is argued that the same semantic principles which result in metaphor productivity for linguistic expressions also result in spatial-graphical expressions.¹

Background

Language gives us words, and constructions made of words, to talk about abstract concepts. We find in space, conventional shapes and organizations of shapes which also convey abstract concepts. These representations in space are typically experienced visually, but not exclusive of other experiential modalities. This paper addresses the problem of how spatial-graphical representations convey abstract meanings by means of metaphors, which allow us to understand or express abstract concepts in terms of concrete expressions, particularly ordinary, relatively static, conventional devices (e.g., map legends, key pads, and clocks).

Fourcville's (1996) analysis of abstract concepts conveyed by creative images and language in advertising, aims toward a theory of 'pictorial metaphor'. Tversky (2001) treats depictions, such as maps, graphics, and icons as involving spatial metaphor derived from concrete world experience, across languages and cultures. Zacks, & Tversky (1999) argue that systematic correspondences between graph forms and interpretation are naturally derived, not due to knowledge of explicit conventions. This paper takes a similar treatment of metaphor, adopting cognitive semantic theory (Clausner, 1993, 1994; Clausner & Croft, 1997; Grady, 1997; Lakoff, 1993; Lakoff & Johnson, 1980; Lakoff & Turner, 1987), which treats metaphor as conventional schemas expressive of ordinary conventional language.

In this theory of metaphor, knowledge is organized into experientially based domains; e.g., SPACE, TIME, LIVING THINGS (see Clausner & Croft, 1999, for an overview of the theory of domains in cognitive semantics). A conventional metaphor is a stored relation between two domains. Concepts from an abstract (target) domain are systematically comprehended or expressed in terms of concepts from a different, often concrete, (source) domain. For example, MORE IS UP AND LESS IS DOWN is a conventional metaphor whose source domain UP-DOWN stands in relation to the target domain MORE-LESS. This metaphor is a semantic structure which can be instantiated as linguistic expressions; e.g., *rising prices, fell ill, high esteem, fell unconscious*.

Language expresses abstract concepts metaphorically by means of spatial and other basic perceptual concepts (Grady, 1997). Metaphors that relate spatial source domains to non-spatial target domains can be productive of linguistic expressions about non-spatial abstract meanings by using words having spatial meanings. The metaphor MORE IS UP is strongly implicated by investigations of graphs as expressions in space. Tversky, Kugelmass & Winter (1991) found that subjects assigned interpretations to the axes of graphs, such that increasing quantity was preferentially assigned to the vertical axis, and temporal concepts were preferentially assigned to the horizontal axis. Gatis & Holyoak (1996) investigated subjects' interpretation of graphs, finding a significant advantage when the variable being queried was assigned to the vertical axis. They argue that graphing increasing quantity in terms of vertical spatial increase is based on the metaphor MORE IS UP. Given that there is evidence for conventional metaphor being expressed in the construal of spatial graphs, this paper proposes the following hypothesis: The same cognitive principles which determine metaphor productivity for linguistic expressions also determine metaphor productivity for spatial expressions. This hypothesis will be tested with respect to a specific technical characterization of metaphor productivity.

Productivity in Metaphors

Clausner & Croft (1997) argue that just as phonological schemas vary in their productivity of base-derived relations, so semantic schemas (i.e., meta-

¹ The author thanks the three anonymous reviewers of this paper for their helpful comments. An earlier version of this research was presented at the Seventh International Cognitive Linguistics Conference, 2001, Santa Barbara, California.

phor source-target domains) also vary in their productivity of metaphorical expressions. Schematicity is the range of source (or target) domain concepts consistent with the schema. Productivity is the proportion of a schema's range which can be instantiated as expressions. This translates into strength of stored representations, called degrees of entrenchment. Relative entrenchment between a schema and its instantiations characterizes its productivity. High productivity of a metaphor is a configuration of a strongly entrenched schema relative to a wide range of weakly entrenched instantiations. Whereas, low productivity of a metaphor is a weakly entrenched schema relative to a narrow range of strongly entrenched instantiations.

In the following sections three degrees of metaphor productivity are considered: High productivity, Semi-productivity, and Nonproductivity. The three cases are presented in separate sections. In each case, the section begins with the conceptual principles by which Clausner and Croft (1997) account for how metaphors vary in their degree of productivity for linguistic expressions. Then evidence that spatial-graphic expressions are metaphorical expressions is presented. Measures from human subjects or semantic analysis are used to argue that in each case the pattern of results is attributable to conceptual principles of metaphor productivity.

High Productivity

The case of a metaphor having high productivity of linguistic expressions is characterized by Clausner & Croft (1997) as follows. The source-target domain relation $[S \rightarrow T]$, is a schema that produces instantiations. Each instantiation $[e \rightarrow c]$ is a metaphorical expression e whose source domain words are about target domain concepts c (Figure 1). For example the metaphor schema $[UP/DOWN \rightarrow MORE/LESS]$ (i.e., MORE IS UP AND LESS IS DOWN) can be instantiated as any number of expressions in which words about verticality (e.g., *rising/falling*, ..., *up/down*) express non-spatial concepts. Metaphor productivity is a semantic configuration of a metaphor and its instantiations which includes the relation of schematicity between schema and instantiations (descending arrows). High productivity is high schema entrenchment (bold box) relative to a wide range of i weakly entrenched instantiations (lighter boxes).

Figure 1: Semantic characterization for high productivity of a metaphor.

A highly productive metaphor expresses a large proportion of concepts consistent with the metaphor schema. Nearly any concept about quantity or quality can be expressed in terms of spatial verticality (e.g., *rising/falling prices*, ..., *feeling up/down*). This characterization of high metaphor productivity for linguistic expressions will be applied to the investigation of metaphor productivity for spatial-graphic expressions.

High productivity (Spatial-graphical metaphorical expressions)

The vertical spatial axis of graphs can be employed to convey quantities and this can be attributed to the metaphor MORE IS UP (e.g., Gatis & Holyoak, 1996). If this metaphor indeed has high productivity and the theory applies to both linguistic and spatial-graphical expressions, then not only numerical quantities, but also non-spatial qualities (e.g., severity) should be found instantiated in space. Specifically, a wide range of concepts about severity is predicted to be expressed such that great severity is expressed as high vertical space. This was measured using assignments of severity to a vertical map legend. The subjects were 34 graduate and undergraduate student interns at HRL Labs. Each subject was given Figure 2 with the instructions, "This is a legend to be used for a weather map of storm severity. As you can see no colors are yet assigned. Assign colors to the two extremes (two boxes) of the legend. Next, (in the blank lines) label which extreme of storm severity is which."

Figure 2: Vertical map legend, uncolored with blanks for labeling the two extreme values.

The aim of color assignment was to first get subjects to commit to a particular orientation of severity (target domain) to verticality (source domain), without having to verbalize target domain concepts. While color names were not expected to be sufficient evidence of any systematic conceptualization of the legend, the labeling of storm severity was expected to evoke words that would demonstrate a preferential orientation consistent with the MORE IS UP metaphor.

Table 1 summarizes the range of types of responses subjects gave as labels for the top and bottom of the legend. The left column lists response types which assign extreme storm severity to the top of the legend (e.g., *severe* and *calm* written in for the top and bottom

labels, respectively). The right column of response types are those which assign extreme storm severity to the bottom of the legend.

Table 1: Response types and percent consistent with MORE IS UP or LESS IS UP, N=34.

MORE SEVERE IS UP / LESS SEVERE IS DOWN	LESS SEVERE IS UP / MORE SEVERE IS DOWN
high / low	low / high
heavy / light	lightest / heaviest
severe / calm	calm / severe
bad / good	
most / least	
severe / less severe	
very severe / not severe	
extreme / clear	
hurricane / balmy	
misery / balmy	
stormy / fair	
91%	9%

Of 34 subject responses, 31 responses assigned greatest severity to the top of the legend and 3 responses assigned the least severity to the bottom. As expected, the assignment of severity to verticality does not occur at a chance rate, but is significantly biased toward the assignment of greater severity to higher verticality, $\chi^2(1, N = 34) = 46.12, p < 0.001$. It can be concluded that something in the cognitive process of doing the task biases the responses, and this bias is consistent with the conventional metaphor MORE IS UP.

Color assignment is not the central task and the results were not expected to bear on the investigation; indeed they are varied. Nonetheless, it is noteworthy that of 34 total color assignment responses, the end of the legend that was also labeled as the most severe (regardless of vertical assignment), was most frequently designated "red" for 68% of color assignments. "Blue" was the most frequent color assigned to the least severe end of the legend for 38% of all color assignments, regardless of vertical assignment.

Figure 3: Graphic-spatial expressions of a highly productive metaphor.

These results suggest that understanding the vertical spatial graphic as a legend of storm severity systematically yields interpretations of the top as an expression of greatest severity, contra the bottom. That is, the subjects read the spatial verticality as an expression of concepts about the abstract quality of severity, such that a significantly large proportion of these concepts are consistent with the *up* part of UP/DOWN SPACE expressing the *more* part of the MORE/LESS quality scale. This characterization of the results is depicted in Figure 3 as a case of many concepts about storm severity (e.g., *severe/calm*, *stormy/fair*, ... and others not shown) as the meanings of the extreme ends of the legend. Each instance of the legend having a particular conceptualization is an expression of a metaphor, as depicted by the arrows between the metaphor MORE/LESS IS UP/DOWN (upper bold box) and each of the instantiations (lower lighter boxes) in Figure 3.

This is the same relation between schema and instantiation illustrated in Figure 1 for linguistic expressions of a metaphor. Just as there are many non-spatial concepts *c* expressed as linguistic expressions *e* using words about vertical space, there are also many non-spatial concepts expressed as spatial-graphs. A large range of non-spatial concepts are consistent with the target domain MORE/LESS and these are expressed by means of a vertical graphical legend consistent with the source domain UP/DOWN, respectively.

It can be concluded that since a large proportion of the schema's range can be instantiated as graphical expressions the metaphor schema is highly entrenched relative to a wide range of weakly entrenched instantiations. The metaphor is highly productive, and of more than the legend colorings and labelings investigated here, but of any graphic vertical axis (e.g., mercury thermometers). Having argued for a case of high metaphor productivity expressed in space, we will next consider cases of lesser productivity.

Semi-Productivity

This section presents an analysis of spatial expressions and argues that they systematically instantiate a semi-productive metaphor. First, the characterization of semi-productive metaphors for linguistic expressions given by Clausner & Croft (1997) is summarized. Then, the case of spatial expressions being instantiations of a semi-productive metaphor is made.

Clausner & Croft (1997) argue that semi-productivity of a metaphor is the case of relatively few linguistic expressions of a metaphor, compared with the wide range of concepts potentially consistent with that metaphor. For example, the five idioms, *spill the beans*, *let the cat out of the bag*, *loose lips*, *blow the whistle*, and *blow the lid off* are all about revealing a secret. Lakoff (1987) and Gibbs & O'Brien's (1990) conclude that

these idioms are consistent with the metaphor schema THE MIND IS A CONTAINER and IDEAS ARE ENTITIES. The idiom expressions are transparent idioms, because most people have some awareness of a relationship between specific word meanings and the idiom meaning. They know that the words for physical things (e.g., cat) escaping a container (e.g., bag) are related to an idiomatic meaning of ideas coming out of the mind. Clausner & Croft's (1997) analysis of these transparent idioms argues that the metaphor schema [ENTITIES OUT OF A CONTAINER → IDEAS OUT OF THE MIND] is semi-productive. There are only five instantiations, each a transparent idiom (e.g., cat out of the bag → secret revealed). The metaphor is only partly productive because the transparent idioms express only a limited proportion of possible instantiations that are consistent with the metaphor. For example, **spill the peas* and **let the weasel out of the cage* are expressions which are consistent with the metaphor schema, but nonetheless do not mean, reveal a secret². The five idioms that do have this meaning are highly conventionalized (i.e., highly entrenched) expressions.

Figure 4: Semantic characterization for semi-productivity of a metaphor.

They conclude that a countable number N of highly entrenched instantiations of a relatively less entrenched metaphor schema is characteristic of metaphor semi-productivity. Figure 4 illustrates the cognitive structure of a lightly entrenched metaphor (lighter box) that is consistent with a limited range of highly entrenched instantiations (bold boxes). Given this account of semi-productive metaphors, semi-productivity for graphical spatial expressions is investigated.

Semi-productivity (Spatial-graphical transparent idioms)

The data considered are the spatial-graphic arrangements of digits for entering numerical values, such as those found on telephones, calculators, alphanumeric keyboards, and rotary telephones (left side of Figures 5-8, respectively). Each of these four digit arrangements is highly conventionalized. It is transparent, however, that the digits are arranged in counting order. That is,

any specific spatial arrangement of digits is understood to be a meaningful ordering of incrementally successive values. That the spatial arrangements vary widely, but have the same interpretation as ordered values, suggests a systematic relation between their spatial expression and their conceptual meaning.

1 2 3	* 0
4 5 6	1 2 3
7 8 9	4 5 6

Figure 6: Calculator key digit pad.

1234567890
* 0123456789

Figure 7: Typing keyboard number order.

Figure 8: Rotary Telephone digit order.

The investigation of a common semantic relation that is consistent among these four spatial arrangements can proceed as one would a linguistic case. Analyzing the range of spatial expressions characterizes the schema that might be instantiating them, just as it does for linguistic expressions. Among these four digit arrangements, the "0" numeral occurs in two positions, either near the "9" numeral, or near the "1" numeral. This suggests that the shared meaning of the digit arrangements is the concept of counting, expressed with the "0" numeral representing either the 0th or 10th value. In fact, the first form of the rotary phone had numbered finger holes, except the "0" was marked with the Roman numeral "X" (Hill, 1953).

If the counting order of digits is indeed the common meaning among the four spatial arrangements, then that order is independent of whether the spatial configuration of the digits is rotational, horizontal, vertical, or

² An asterisk, "*", which begins a linguistic expression or graphic expression denotes its infelicity as a conventional expression of the particular semantic meaning in discussion.

some combination (e.g., reading “1” to “9” successively left-to-right and top-to-bottom, as on a phone pad). These configurations (or combinations, of them) are expressed, but it is the counting order, not the spatial order, that is common across the expressions. The only variation among digit orderings is the relative position of “0” in the counting order.

In laying out a metaphorical system of how humans understand abstract mathematical concepts Lakoff & Núñez (2000) propose metaphors which fit the above analysis. They first establish that MODULAR ARITHMETIC IS ALGEBRAIC GROUPS and GEOMETRIC ROTATIONS ARE ALGEBRAIC GROUPS. That is, the digits for counting in base 10 modular math are conceptualized as rotations. Successive rotations form the basis for counting, which they argue is the metaphor THE INFINITE CLASS OF NUMERALS FOR THE NATURAL NUMBERS IS AN ITERATIVE PROCESS THAT GOES ON AND ON. For the purpose of this paper, the simpler characterization is [CYCLIC PROCESS → COUNTING WITH DIGITS]. The spatial expression of the CYCLE in this case is the spatial traversal of numerals in one of four conventional arrangements. The traversal is cyclic by means of the “0” indicating modulo 10.

Evidence that the metaphor does not express the full range of spatial expressions consistent with its specifications comes from the absence of specific digit arrangements. The right side of Figures 5-8, depict spatial arrangements of digits that are unexpressed as conventional digit orders (as denoted by “*”). These spatial arrangements are consistent with base 10 counting order, but they are not conventionalized.

Figure 9 depicts the metaphor (upper light box) which is semi-productive of N highly conventionalized instantiations (lower bold boxes). The $N=4$ spatial arrangements of numerals are understood as ordered digits. The metaphor is semi-productive, because the four instantiations are consistent with the metaphor, which is not productive of other expressions.

Figure 9: Graphic-spatial expressions of a semi-productive metaphor.

The case of spatial expressions of semi-productive metaphor can be called, “transparent spatial-graphic

idioms”. Transparent linguistic idioms are highly entrenched expressions of a comparatively lightly entrenched metaphor (Figure 4). This same principle of semi-productivity applies to spatial expressions. Only four of the possible spatial arrangements consistent with the metaphor domain relation are expressed. The expressed spatial arrangements are highly conventional and their meaning is semantically transparent.

Nonproductivity

This section investigates productivity less in degree than semi-productive metaphor, specifically the case of nonproductivity. Opaque linguistic idioms are very few. For example, *kick the bucket*, meaning to die, and *by and large*, meaning something in general. They are semantically opaque in that most English speakers know these linguistic expressions and know what they mean, but do not know why they make sense. Clausner & Croft (1997) analyze *save face* and *lose face* as opaque linguistic expressions of an absent metaphor. The expressions were borrowed from Mandarin Chinese. English speakers know their meaning is about avoiding disgrace and incurring disgrace, but they do not know why they mean this. English lacks the relevant metaphor [HAVING FACE → SOCIAL RESPECT] that would be productive of other expressions, such as those not borrowed into English, e.g., **give face*, does not mean, to show due respect for someone’s feelings, as it does in Mandarin.

Figure 10 depicts the absence of an entrenched metaphor schema (light dashed box). The expression is extremely conventional, that is, highly entrenched (bold box), and it is opaque since there is no source-target domain relation that would be productive of the expression e in relation to concept c . Also absent are vertical arrows, indicative of the nonproductivity.

Figure 10: Semantic characterization for metaphor nonproductivity.

Now we turn to graphical-spatial expressions and argue that we find the same semantic structure as for opaque linguistic idioms.

Nonproductivity (Spatial-graphical opaque idioms)

An extremely conventional spatial-graphical expression is the analog clock. There are clockwise clocks, but not counter-clockwise clocks (although they exist for

amusement, but not conventional use). Most people do not know why clocks run in the conventional clockwise direction. It is opaque, in that there is no conventional semantic relation between the source and target which makes the spatial pattern make sense. That is, there is no widespread knowledge that the sidereal rotational direction of shadows cast by sundials in the northern hemisphere is the basis for the rotational direction of clocks. There is no conventional entrenched metaphor schema. If there were a metaphor it might be something like, *PASSAGE OF TIME IS SHADOW ROTATION*.

Just as there are few opaque linguistic idioms, it should follow that there are few "opaque spatial idioms", precisely because there is no conventional metaphor to produce them. Another example of an opaque spatial idiom would be the QWERTY keyboard³. The arrangement of alphanumeric keys is widely known, but why they have this specific arrangement, among all the possible unattested ones, is largely opaque. It is not widely known that early mechanical typewriters arranged keys in order to slow typing speed, thus reducing the likelihood of two keys striking together.

Discussion and Conclusion

These results point to issues of representation and conceptual structure common to linguistic semantics (spoken and signed), psychology, computational modeling and the role of metaphor in human-computer interaction. Further work is required to distinguish the theory of metaphor productivity from alternate interpretations of the results, e.g., treating conventional correlations between the top of a spatial axis and one pole of a semantic scale as due to salience. The top of a legend or vertical mercury thermometer, or keypad digit ordering may be interactions of perception and conventionality; however, conventionalized form-meaning pairs do not obviate a conventional metaphor schema. The theory of productivity is about contemporary conceptual structure (not historical origins of the metaphors) and predicts the above results.

Spatial-graphical expressions are argued to be instantiations of conceptual metaphors which vary in productivity according to the same principles which determine productivity for linguistic expressions. The relative entrenchment of a metaphor to its instantiations is argued to result in varying ranges of expressions. Three degrees of metaphor productivity were investigated. In each case the principles which are held to explain ranges of linguistic expressions are argued to explain evidence about spatial graphical expressions. These are, in decreasing order: High productivity is the case of spatial-graphical metaphorical expressions. Semi-productivity is the case of spatial-graphical trans-

parent idioms. Nonproductivity is the case of spatial-graphical opaque idioms. These cases are concluded to represent three points on a continuum of metaphor productivity for spatial-graphical expressions.

Abstract

Words seem to have a special status among perceptual signals. The developmental evidence, however, suggests that words *become* special. Woodward and Hoyne (1999) showed that 13-month-olds readily associate both words coming from the experimenter's mouth and non-linguistic sounds coming from a hand-held noisemaker, with object categories. In contrast, 20-month-olds associate words but not non-linguistic sounds with object categories. Woodward and Hoyne suggest that words become privileged as possible names; that the forms a name can take are open at the beginning and become more restricted with development. Are children learning what forms count as words? If so, just what defining features are they learning? This paper presents an associationist account of this developmental trend and tests this explanation in two experiments with 20-26-month-old children.

Introduction

Words seem to have a special status among perceptual signals. Having a label for an object changes the way it is categorized for both adults and children. For example, when asked to generalize an object name to new instances, children and adults generalize by shape. However, when asked to find an object that "goes with" another, they choose by overall similarity (Landau, Smith & Jones, 1988; Imai & Gentner, 1997). A label also makes children's choices shift from thematic to taxonomic (Waxman, 1997) and from surface to more conceptual similarities (Keil, 1989). As Waxman said, words work like invitations to form categories; words are category names. But what makes a word? How do children know whether a particular sound is a category label?

One finding critical to this issues was reported by Woodward and Hoyne (1999). They presented children with two novel objects and labeled one of them (the target object). In the Word condition they paired the target object with a word ("this is a toma"); in the Sound condition they paired the target object with a non-linguistic sound, such as a tone. Children were then asked to "get the toma" or "get the < tone >" to test whether they had associated the "label" (toma or < tone >) with the object. They asked: Do children treat only words as

possible names or do they also accept tones as possible names? Their results indicate that the answer to this question depends on the developmental level of the child. Thirteen month-old infants will associate both a word and a non-linguistic sound with a target object. In contrast, 20-month-old children will associate a word to a target object, but not a non-linguistic sound. Namy & Waxman (1998) have similar results for 18- and 26-month-olds contrasting words and gestures. While the younger children will associate both a novel word and a novel gesture with a target object (object category) the older children will only associate the word to the object, and not the gesture.

Both teams of researchers suggest that older children do not associate non-words with the objects because older children know that non-words are not possible names. The idea is that words become privileged as possible names; that the forms a name can take are open at the beginning and become more restricted with development. But how do words become names and thus privileged? What determines what counts as a name?

In this paper we attempt to answer these questions. First we offer a mechanistic explanation of this developmental trend. Then we present two experiments that test our explanation.

An associationist account

We propose that words become privileged as category names because of the special way in which they correlate with object categories. In the experience of a child, many events may co-occur with attention to objects. For example, objects may co-occur with expressions such as "look!", gestures such as pointing, words related or unrelated to the object, noises, actions related or unrelated to the nature of the object, and so on. However, of all these events, words (as object names) correlate in a way that makes them especially good predictors for category membership.

By our account, there are two properties that make words good candidates for becoming privileged as names. The first property is predictiveness or cue validity. There is one name (more or less) that goes with one category (more or less). Thus, the name of

a category is a feature that all members of the category have in common, while at the same time the name is a feature that distinguishes instances of the named category from members of other categories. This is illustrated in Figure 1. The word “ball” typically co-occurs with members of the category BALL, but not with members of the category DOG. Similarly, the word “dog” co-occurs with members of the category DOG, but not with members of the category BALL. In contrast, events like pointing and hearing “look!” will just as likely co-occur with both balls and dogs. Thus, it is the object names that are predictive of object category, and not events like pointing or the word “look!”.

Figure 1: Object names systematically correlate with object categories

Predictiveness, however, is not enough by itself. After all, even 3-4 month-old infants can distinguish pictures of dogs from, for example, cars. Whether infants have the category or concept of DOG or CAR or not, the fact remains that there is something about dogs and cars perceptually that allows them to distinguish members of the two categories. Why isn't the feature “dogness” (or “cariness”) which is predictive of category membership for the category DOG (or CAR) not something that can be taken as a name, like a word? We propose that the answer to this question lies in a second statistical property: systematicity. That is, words as a *domain* are predictive of object category membership. Put another way, if there were just one word that correlated with a category, words in general would not get an advantage. The fact that there are many words that co-occur with many object categories is what helps children generalize this expectation to novel words.

The mechanism we propose also says something about the nature of words as names. According to our account, a name is simply the bundle of signals that systematically co-occurs with categories. These could be properties such as being a speech sound with particular spectral and prosodic forms, being produced by people, coming out of mouths, or co-occurring with pointing and eye gaze to the object.

Thus, these may be the properties that, through language learning, come to define what counts as a name for children.

In sum, in our account what makes words privileged as names is that they co-occur systematically with object categories. Conversely, a name is whatever features systematically co-occur with object categories, even beyond what we usually think of as words (or names).

Thus, we make the following two predictions:

1. Events that co-occur systematically with object categories come to refer — to be usable as names. According to our account, any event domain that systematically predicts category membership will be taken as a name as well. Fortunately for the experiment we report here, children's experiences include a domain in which something other than words co-occurs systematically with categories — the domain of animals. Animal category correlates with animal sound: dogs bark, cats meow, elephants trumpet and so on. Thus our first prediction is that animal sounds should be taken as names for animals.
2. What defines a name is the cluster of features that systematically co-occurs with categories. This means that any strongly correlated feature of a name, even beyond what we think of as a word, will become an integral part of what is a name. For young children who rely on spoken language, words emanating from mouths is a highly systematic property of names. Therefore children should take coming-from-a-mouth as one of the defining features of being a name. Thus, our second prediction is that if a word comes out of a place other than a mouth, young children will not take it as a name. Conversely, young children may take a non-word as a name if it emerges from a mouth.

In the next experiment we tested these predictions in the domain of animals. We selected children to participate who by Woodward & Hoyne's and Namy and Waxman's studies should already treat words as the only privileged naming events. To test the first prediction (that animal sounds can be used as names for animals) we labeled animal toys with different kinds of sounds: a word, an animal sound, and a motor sound. To test the second prediction (that emanating from the mouth was a defining feature of being a name) we made the names emanate from different sources: from the experimenter's mouth or from a nearby object.

The design for Experiment 1 is shown in Figure 2. Note that from Woodward and Hoyne's study we know what will happen in the Word-Mouth cell and in the ArbitrarySound-Noise-maker cell. Children should take the word as a name in the first case and reject the sound as a name in the second case. The questions are: will they accept the animal sound as a

name? Will they accept any kind of sound emanating from the mouth as a name? Will they accept the word as a name regardless of where it comes from, or will the source matter?

		Source	
		Mouth	NoiseMaker
Sound	Word		
	Animal Sound		
	Motor Sound		

Figure 2: The experiment had three different kinds of sound (Word, Animal Sound, Arbitrary Sound) as within-subject conditions and two different sources (Mouth, Noisemaker) as between-subject conditions

Experiment 1

Methods

Subjects. 24 20-26 month-old children participated in the experiment.

Design. We used a 2x3 mixed design with the two different sources (mouth, noisemaker) as a between-subject variable and the three different sounds (word, animal sound, arbitrary sound) as a within-subject variable.

Stimuli. The stimuli consisted of two sets of six novel toy animals. The animals in the two sets were the same in all respects except in color, and one was used as the generalization of the other. The sounds used as names were the word "toma", a frog sound as the animal sound, and a motor sound as the arbitrary sound.

Procedure. The experiment was preceded by a training phase. The goal of the training phase was to make sure that the child understood the task and could make clear choices. In this phase we presented the child with a familiar object (a ball, a spoon, a flower) and asked the child to "get the ball" (or spoon or flower). Once the child had done this, we put two familiar objects on the tray and asked the child to get one of them. The training was considered successful if the child retrieved the correct object twice from the tray with a distracter.

Each child heard three different kinds of names (Word, Animal Sound, Motor Sound) in three blocks. Each block consisted of a Familiarization phase and a Test phase.

In the Familiarization phase the child was shown two different toy animals and a name was supplied for one of them – the target object. The two objects were presented twice, one toy animal at a time. First the target animal was presented and named, and then the distracter animal was presented with the same phrases but without a name. Then the target animal was presented and named again followed by the distracter animal.

In the Mouth condition, children heard the three kinds of label coming from the experimenter's mouth. When presenting the target object, the experimenter named it saying, "Look at this toma. Wow! See this toma? Look! Toma." in the Word condition, imitated the animal sound in the Animal Sound condition ("look at this < frog-likeclucking >") and imitated the mechanical sound in the Motor Sound condition ("look at this < motor-likesound >"). In the Noisemaker condition the three kinds of sounds came from cloth-covered recorders that were held close to the toy animal being named. The distracter objects were always presented with the same phrases as the target objects, but without the name: "Look at this! Wow! See this? Look!"

In the Test phase the child was presented with two choices on a tray and asked to retrieve the target object. The test question was asked in the same manner as the naming in each condition – from the mouth in the Mouth condition and from the Noisemaker in the Noisemaker condition. There were four test trials for each kind of sound; two test trials used the same animals as the ones used in the Familiarization phase and the other two were generalization trials, using the animals that matched the familiar ones in all aspects except for their color. Each child got a total of 12 trials. The toys were randomly assigned to each condition for each child. The order of the two sound type conditions was counterbalanced.

Results

We coded children's choices as the first object they touched or took from the tray. Figures 3 and 4 show the number of children who successfully mapped the name to the object category in the Word, Animal Sound and Motor Sound conditions. We classified children as Successfully Mapping if they picked the target object when asked on three or more of the four trials.

Figure 3 shows children's performance. In the Word condition, most children (9 out of 12) successfully mapped the word to the animal category when the word came from the experimenter's mouth. The number of children that successfully mapped the word to the animal category in the Mouth condition was reliably more than would be expected by chance ($p < .01$). In contrast, the number of Successfully Mapping children in the Noisemaker condition was almost reliably below what would be expected by

Figure 3: Results of Experiment 1. Any sound emanating from the mouth is taken as a name and animal sounds are taken as names regardless of its source

Figure 4: Results of Experiment 2. Any sound emanating from the mouth is taken as a name and motor sounds are taken as names regardless of its source

chance ($p = .06$). In fact, only one child consistently retrieved the target object when the name was a word coming from a handheld noisemaker. Thus, it appears that children *only* accept the word as the name of an animal category when the word emanates from the mouth of the experimenter.

In the Animal Sound condition, the number of the Successfully Mapping children exceeded what would be expected by chance in both source conditions (Mouth: $p = .01$, Noisemaker: $p = .03$). That is, children successfully mapped the animal sound to the animal category regardless of the source of the sound. They did so whether the sound came from the experimenter's mouth or from a handheld noisemaker. So, children always accept the animal sound as the name of an animal category, regardless of the source from which the animal sound emanates.

In the Motor Sound condition – when the sound used was an unrelated sound – the number of children successfully mapping the sound to the animal category only exceeded what would be expected by chance in the Mouth condition ($p < .05$). The number of children that successfully mapped the me-

chanical sound with the animal category when the sound came from the Noisemaker did not reliably exceed chance ($p > .2$). That is, motor sounds are only accepted as names when they emanate from a mouth.

In short, any sound emanating from the mouth is taken as a name and animal sounds are taken as names regardless of its source.

Discussion

Our results replicate Woodard and Hoyne's study: words emanating from mouths are associated with object categories and arbitrary sounds emanating from handheld noisemakers are not associated with object categories. In addition to that, however, we have shown two things. First, that words are only accepted as names when they come from the speaker's mouth, and not when they come from other sources, such as a hand-held noisemaker. Second, that even non-linguistic sounds, such as the buzz of a motor or the croak of a frog, will be taken as a name if they are produced by a human mouth. Therefore, our results suggest that for children at this age it is not words that are taken as the privileged form of naming, but rather sounds produced by a human mouth, that is, source matters.

One difference in our results between words and animal sounds is that the source of the name matters for the word, but not for the animal sound. This also fits with our associationist account: in children's experience, animal sounds are not specific to a source. They emanate from the mouths of real animals, from the inside of stuffed animal toys, and from mouths of people imitating animals. In contrast, words – as object names – are typically produced by human mouths. Therefore the source will be part of what defines a word as a name, but not of what defines an animal sound as a name for an animal category.

Why are sounds emanating from mouths always taken as names? According to our account, this is because emanating from a mouth is one of the most systematically correlating features of naming situations. Another possibility that needs to be explored is that perhaps when produced by a human mouth even an imitation of a mechanical sound stops being arbitrary. Being made by a mouth may make any sound word-like (or animal sound-like).

More importantly for our proposal, however, our results showed that animal sounds – which are systematically correlated with animal categories in the real world – will be accepted as labels for animal categories regardless of their source. Thus, our predictions were confirmed.

Why are animal sounds taken as names for animal categories? According to our proposal, this is because animal sounds correlate with animal categories in much the same way as words correlate with object categories in general: one animal sound corresponds to one animal category, and animals typically

are associated with a sound they make. However, an alternative explanation is that there is something in the acoustic features of the animal sound used that makes it word-like. That is, it may be that it is not the special way in which animal sounds correlate with animal categories which makes animal sounds good potential labels for animal categories, but that there is something about animal sounds (perhaps they are closer to linguistic sounds in some similarity space), that makes them good potential labels for any category. Conversely, it could be that motor sounds are just not word-like enough to serve as a label. Thus, to support our proposal we have to show that animal sounds are good *only* for animal categories (and not vehicle categories), and that motor sounds are good *only* for vehicle categories (and not animal categories). Accordingly, in the next experiment we test this alternative explanation by replicating Experiment 1 using toy vehicles instead of toy animals as stimuli.

We reasoned that vehicle sounds correlate with vehicle categories much in the same way as animal sounds correlate with animal categories. Thus, if our account is right, and it is the systematicity of correlations that makes a word, we predict that contrary to what was found in Experiment 1, the motor sound (now related) will be accepted as a name for toy vehicles, but the animal sound (now unrelated) will not. However, if it is something specific about the animal sound we used that made it work as a name, the same animal sound should be accepted as a name for vehicle categories as well.

Experiment 2

Subjects. 24 20-26 month-old children participated in the experiment.

Design. As in Experiment 1, we used a 2x3 mixed design with the two different sources (mouth, noisemaker) as a between-subject variable and the three different sounds (word, animal sound, motor sound) as a within-subject variable.

Stimuli. The stimuli consisted of two sets of six novel toy vehicles. We used the same sounds as in Experiment 1, that is the word "toma", a frog sound, and a motor sound.

Procedure. The procedure is the same as in Experiment 1.

Results

Children's choices were coded as in Experiment 1. Children were classified as Successfully Mapping according to the same criterion as in Experiment 1 – when they chose the target object correctly in at least 3 of the 4 trials. The results of Experiment 2

are analogous to the results of Experiment 1. Children map the motor sound to vehicle categories, but fail to map the animal sound – the unrelated sound.

Figure 4 shows children's performance in Experiment 2. In the Word condition, most children (10 out of 12) successfully mapped the word to the animal category when the word came from the experimenter's mouth. The number of children that successfully mapped the word to the animal category in the Mouth condition was reliably more than would be expected by chance ($p < .01$). In contrast, the number of Successfully Mapping children in the Noisemaker condition was not different from chance ($p > .2$). Thus, as in Experiment 1, children accept the word as the name of a vehicle category only when the word emanates from the mouth of the experimenter.

In the Animal Sound condition, when the sound used as name was a unrelated to the vehicle categories, the number of children successfully mapping the sound to the animal category only exceeded what would be expected by chance in the Mouth condition ($p < .05$). The number of children that successfully mapped the animal sound with the vehicle category when the sound came from the Noisemaker did not reliably exceed chance ($p > .2$). That is, animal sounds are only accepted as names for vehicle categories when they emanate from a mouth.

In the Motor Sound condition, when the sound was systematically related to vehicle categories, the number of the Successfully Mapping children exceeded what would be expected by chance in both conditions (Mouth: $p = .01$, Noisemaker: $p = .03$). That is, children successfully associated the motor sound to the vehicle category regardless of the source of the sound. So, children seem to accept the motor sound as the name of an vehicle category, regardless of the source from which the motor sound emanates.

In short, as in Experiment 1, any sound emanating from the mouth is taken as a name and related sounds (in this case motor sounds) are taken as names regardless of their source.

Discussion

In Experiment 1, the pattern of results could be explained away by suggesting that there was something special about the animal sound used in the experiment, or animal sounds in general, that made it more word-like. By using the same sounds as in Experiment 1, but showing the opposite pattern of results (Animal sound not taken as a label; Motor sound taken as a label), we showed this is not the case. Which non-linguistic sound will be more readily associated with an object category depends on the kind of object categories being associated: if the categories are from the domain of animals, then the animal sound will have the advantage; if the categories are from the domain of vehicles, then the motor sound will have the advantage.

Furthermore, Experiment 2 provided converging evidence from a different domain for the idea that systematically correlating cues become good candidates for label-hood. The results of this experiment agree with the results of Experiment 1. That is, children in Experiment 2, like children in Experiment 1, were likely to map the related non-linguistic sound to the object categories, but not the unrelated non-linguistic sound.

Conclusions

The results of the two experiments showed the same pattern: Words, as well as non-linguistic sounds that systematically correlate with the relevant domain of categories, are accepted as labels. In contrast, non-linguistic sounds that are unrelated to the domain in question are not accepted as labels. Furthermore, words are only accepted as labels when they are produced by a mouth. Why this pattern? We believe that this pattern reflects the systematicity with which events correlate with categories in the world. Sounds from mouths typically name things, so they are taken as names even when they have unusual properties such as the imitation of a mechanical sound does. Animal sounds systematically correlate with animal categories, so these kinds of sound – from mouths or from noisemakers – are accepted as names for animal categories. Analogously, motor sounds systematically correlate with vehicle categories, so these kinds of sound – regardless of their source – are accepted as names for vehicle categories.

Perhaps, before language learning, there is nothing special about words as names and there is nothing special about reference. All that a word is is a bundle of highly correlating features. All that reference is, is the association between a name – the bundle of highly correlating features – and a category. Maybe children learn what is reference as they learn names, and they learn names as they experience words referring to object categories.

With more learning, what counts as a name should get more and more abstract, to the point in which emanating from a mouth may no longer be a crucial feature. However, this may be where it starts; in the systematicity with which events, such as spoken words or animal sounds, refer to categories.

Sequential Learning by Touch, Vision, and Audition

Christopher M. Conway (cmc82@cornell.edu)

Morten H. Christiansen (mhc27@cornell.edu)

Department of Psychology
Cornell University
Ithaca, NY 14853, USA

Abstract

We investigated the extent to which touch, vision, and audition are similar in the ways they mediate the processing of statistical regularities within sequential input. While previous research has examined statistical/sequential learning in the visual and auditory domains, few researchers have conducted rigorous comparisons across sensory modalities; in particular, the sense of touch has been virtually ignored in such research. Our data reveal commonalities between the ways in which these three modalities afford the learning of sequential information. However, the data also suggest that in terms of sequential learning, audition is superior to the other two senses. We discuss these findings in terms of whether statistical/sequential learning is likely to consist of a single, unitary mechanism or multiple, modality-constrained ones.

Introduction

The acquisition of statistical/sequential information from the environment appears to be involved in many learning situations, ranging from speech segmentation (Saffran, Newport, & Aslin, 1996), to learning orthographic regularities of written words (Pacton, Perruchet, Fayol, & Cleeremans, 2001) to processing visual scenes (Fiser & Aslin, 2002). However, previous research, focusing exclusively on visual and auditory domains, has failed to investigate whether such learning can occur via touch. Perhaps more importantly, few studies have attempted directly to compare sequential learning as it occurs across the various sensory modalities.

There are important reasons to pursue such avenues of study. First, a common assumption is that statistical/sequential learning is a broad, domain-general ability (e.g., Kirkham, Slemmer, & Johnson, 2002). But in order to adequately assess this hypothesis, systematic experimentation across the modalities is necessary. If differences exist between sequential learning in the various senses, it may reflect the operation of multiple mechanisms, rather than a single process. Second, in regards to the touch modality in particular, prior research has generally focused on low-level perception; discovering that the sense of touch can accommodate complex sequential learning may have important implications for tactile communication systems.

This paper describes three experiments conducted with the aim to assess sequential learning in three

sensory modalities: touch, vision, and audition. Experiment 1 provides the first direct evidence for a fairly complex tactile sequential learning capability. Experiment 2 provides a visual analogue of Experiment 1 and suggests commonalities between visual and tactile sequential learning. Finally, Experiment 3 assesses the auditory domain, revealing an auditory advantage for sequential processing. We conclude by discussing these results in relation to basic issues of cognitive and neural organization—namely, to what extent sequential learning consists of a single or multiple mechanisms.

Sequential Learning

We define sequential learning as an ability to encode and represent the order of discrete elements occurring in a sequence (Conway & Christiansen, 2001). Importantly, we consider a crucial aspect of sequential learning to be the acquisition of statistical regularities occurring among sequence elements. Artificial grammar learning (AGL; Reber, 1967) is a widely used paradigm for studying such sequential learning¹. AGL experiments typically use finite-state grammars to generate the stimuli; in such grammars, a transition from one state to the next produces an element of the sequence. For example, in the grammar of Figure 1, the path begins at the left-most node, labeled *S1*. The next transition can lead to either *S2* or *S3*. Every time a number is encountered in the transition between states, it is added as the next element of the sequence, producing a sequence corresponding to the rules of the grammar. For example, by passing through the nodes *S1*, *S2*, *S2*, *S4*, *S3*, *S5*, the “legal” sequence 4-1-3-5-2 is generated.

During a training phase, participants typically are exposed to a subset of legal sequences—often under the guise of a “memory experiment” or some other such task—with the intent that they will incidentally encode structural aspects of the stimuli. Next, they are tested on whether they can classify novel sequences as

¹In the typical AGL task, the stimulus elements are presented simultaneously (e.g., letter strings)—rather than sequentially (i.e., one element at a time). We consider even the former case to be a sequential learning task because scanning strings of letters generally occurs in a left-to-right, sequential manner. However, our aim here is to create a truly sequential learning environment using temporally-distributed input.

incorporating the same regularities they had observed in the training input. Participants commonly achieve levels of correct classification that are significantly greater than chance. Although there has been disagreement as to what types of information participants use to make correct classification judgments, it is likely that statistical information is an essential piece of the puzzle (e.g., Redington & Chater, 1996). Participants appear to become sensitive to the statistical regularities in the training items—i.e., the frequency with which certain “chunks” of information co-occur—allowing them to generalize their knowledge to novel sequences. It is such statistical sensitivity that we consider to be vital for complex sequential learning tasks.

Figure 1: The finite-state grammar used to generate the stimuli for the three experiments.

The standard AGL paradigm has been used extensively to assess visual, as well as auditory learning, suggesting that sequential learning can occur in both modalities. However, two issues remain unexplored: can sequential learning occur in other modalities, such as touch? And, what differences in sequential learning, if any, exist between different sensory modalities?

Experiment 1: Tactile Sequential Learning

The touch sense has been studied extensively in terms of its perceptual and psychophysical attributes (for a review, see Craig & Rollman, 1999), yet only a few studies have hinted that complex sequential learning is possible. For instance, evidence suggests that tactile temporal processing and pattern learning is better than visual, but worse than auditory processing (e.g., Handel & Buffardi, 1969; Manning, Pasquali, & Smith, 1975; Sherrick & Cholewiak, 1986). These studies suggest that touch supports a powerful learning mechanism, which perhaps may be sufficient to allow for successful performance on an AGL task. Experiment 1 attempted to verify this hypothesis.

Method

Participants A total of 20 undergraduates (10 in each condition) from introductory Psychology classes at Southern Illinois University, Carbondale, participated in the experiment. Subjects earned course credit for their participation. The data from an additional five participants were excluded for the following reasons: prior participation in AGL tasks in our laboratory ($n=4$); did not adequately follow the instructions ($n=1$).

Apparatus The experiment was conducted using the PsyScope presentation software (Cohen, MacWhinney, Flatt, & Provost, 1993) run on an Apple G3 PowerPC computer. Participants made their responses using an input/output button box (New Micros, Inc., Dallas, TX). Five small motors, normally used in hand-held paging devices, generated the vibrotactile pulses. Each of these motors was less than 18 mm long and 5 mm wide, making them small enough to be easily attached to the participants' fingers with velcro straps. When activated, the motors produced minor vibrations (rated at 150 Hz) at a magnitude equal to that found in hand-held pagers.

The motors were controlled by output signals originating from the New Micros button box. These control signals were in turn determined by the PsyScope program, allowing precise control over the timing and duration of each vibration stimulus.

Materials The stimuli used for Experiment 1 were taken from Gomez and Gerken's (1999) Experiment 2. This grammar (see Figure 1) can generate up to 23 sequences between 3 and 6 elements in length. The grammar generates sequences of elements (numbers) with each number being mapped onto a particular finger (1 is the thumb and 5 is the pinky finger). Each tactile stimulus consisted of a sequence of vibration pulses (pulse duration of 250 ms) delivered to the fingers, one finger at a time (250 ms occurring between pulses). For example, the legal sequence 1-2-5-5 corresponds to one vibration pulse delivered to the thumb, then a pulse to the second finger, and lastly two pulses to the fifth finger.

A total of 12 legal sequences, arranged into pairs, were used for training. Six pairs consisted of one training sequence presented twice (matched pairs) whereas the remaining six pairs consisted of two sequences that differed slightly from one another (mismatched pairs). A 2 s pause occurred between the two sequences of each pair.²

The test set consisted of ten legal and ten illegal sequences, all of which were novel to the participants. Illegal sequences were produced by beginning each with a legal element, followed by a series of illegal

² An example of a matched pair is 4-1-3, 4-1-3; an example of a mismatched pair is 1-2-5-5, 1-2-1-3.

transitions, and ending with a legal element once more. An illegal transition denotes that a particular pair of elements does not occur together during training. For example, the illegal sequence 4-2-1-5-3 begins and ends with legal elements (4 and 3, respectively) but contains several illegal interior transitions (4-2, 1-5, and 5-3 do not occur during training). In this manner, the legal and illegal sequences differ from one another in terms of the statistical relationships of adjacent elements.³

Procedure Participants were assigned randomly to either a control group or an experimental group. The experimental group participated in both a training and a testing phase, whereas the control group only participated in the testing phase. Before beginning the experiment, participants were assessed by the Edinburgh Handedness Inventory (Oldfield, 1971) to determine their preferred hand. Then, using velcro straps, the experimenter placed a vibration device onto each of the five fingers of the preferred hand.

At the beginning of the training phase, the experimental participants were instructed that they were participating in a sensory experiment in which they would feel pairs of vibration sequences. For each pair of sequences, they had to decide whether the two sequences were the same or not, and indicate their decision by pressing a button marked "YES" or "NO". This match-mismatch paradigm used the twelve training pairs described earlier. It was our intention that this paradigm would encourage participants to pay attention to the stimuli while still allowing incidental learning of the statistical structure to occur.

After the last sequence of each pair, a 1 s pause occurred, followed by a prompt on the screen asking for the participant's response. After the participant made a response, there was a 2 s inter-trial interval before the next pair began.

Each pair was presented six times in random order for a total of 72 exposures, the entire training phase lasting roughly ten minutes. A recording of white noise was played during training to mask the sounds of the vibrators. In addition, the participants' hands were covered by a cardboard box so that they could not visually observe their fingers. These precautions were taken to ensure that tactile information alone, without help from auditory or visual senses, contributed to task performance. As mentioned previously, the experimental group—but not the control group—participated in the training phase.

Before the beginning of the testing phase, the experimental participants were told that the vibration sequences they had just felt had been generated by a

computer program that, using a complex set of rules, determined the order of the pulses. They were told that they would now be presented with new vibration sequences. Some of these would be generated by the same program while others would not. It was the participant's task to classify each new sequence accordingly (i.e., whether or not the sequence was generated by the same program) by pressing a button marked either "YES" or "NO." The control participants received the same instructions and task except that there was no reference made to a previous training phase.

The twenty test sequences were presented one at a time, in random order, to each participant. The timing of the test sequences was the same as that used for the training sequences.

Results

The training performance for each experimental participant was assessed by calculating the mean percentage of correctly classified pairs. This calculation revealed that participants, on average, made correct match-mismatch decisions for 74% of the trials.

Results from the testing phase revealed that the control group correctly classified 45% of the test sequences while the experimental group correctly classified 62% of the test sequences. Following Redington and Chater's (1996) suggestions, two analyses were conducted on the data. The first was a one-way analysis of variance (ANOVA; experimental vs. control group) to determine whether any differences existed between the two groups. The second compared performance for each group to chance performance (50%) using single group t-tests.⁴

The ANOVA revealed that the main effect of group was significant, $F(1, 18) = 3.16, p < .01$, indicating that the experimental group performed significantly better than the control group. Single group t-tests confirmed the ANOVA's finding. The control group's performance was not significantly different from chance, $t(9) = -1.43, p = .186$, whereas the experimental group's performance was significantly above chance, $t(9) = 2.97, p < .05$.

The results show that the experimental group significantly outperformed the control group. This suggests that the experimental participants learned aspects of the adjacent element statistics inherent in the training sequences, allowing them to classify novel test sequences appropriately. This is the first empirical evidence of a tactile sequential learning system of such complexity to enable participants to make judgments regarding the legality of artificial grammar-generated sequences.

³In addition, Gomez and Gerken (1999) matched the legal and illegal sequences in terms of element frequencies and length so that these factors could not influence performance.

⁴Ideally, the control group should perform at chance levels while the experimental group should perform significantly better than both chance and the control group.

Experiment 2: Visual Sequential Learning

Experiment 2 assessed sequential learning in the visual domain. This experiment was identical to Experiment 1 in terms of the general procedure and the timing of the stimuli; however, instead of vibrotactile pulses, the sequences consisted of flashing squares occurring at different spatial locations. The reason for using such stimuli, as opposed to letters, for example, was to provide as close a match as possible to the tactile stimuli used in the first experiment. Importantly, unlike sequences of letters, the vibrotactile sequences consisted of non-linguistic, spatially-distinct elements that were presented one at a time (sequentially). The visual stimuli used for this second experiment shared these same characteristics; therefore, the resulting data should provide a meaningful basis for comparison with the first experiment. Like Experiment 1, there was an experimental group, undergoing training and testing phases, and a control group, undergoing the testing phase only.

Only a handful of statistical learning studies have used non-linguistic visual stimuli in a truly sequential manner (e.g., Fiser & Aslin, 2002; Kirkham et al, 2002). The data suggest that such a presentation does not hamper sequential learning by vision. However, other studies (e.g., Handel & Buffardi, 1969) indicate that for certain temporal processing and pattern learning tasks, vision may be inferior to touch. This experiment aimed to investigate whether such differences would be observed.

Method

Participants An additional 20 undergraduates (10 in each condition) were recruited from introductory Psychology classes at Cornell University. Subjects received extra credit for their participation. The data from three additional participants were excluded for the following reasons: did not adequately follow the instructions ($n=2$); equipment malfunction ($n=1$).

Apparatus The apparatus was the same as Experiment 1, except for the exclusion of the vibration devices.

Materials The sequences were identical to those of Experiment 1 except that instead of vibrotactile pulses, they were composed of flashing black squares displayed on the computer monitor (1 was the leftmost location and 5 was the rightmost). Each flashing square appeared for 250 ms and was separated by 250 ms. Thus, 1-2-5-5 represents a sequence consisting of a flash appearing in the first location, then in the second location, followed by two flashes in the fifth location.

Procedure The procedure was the same as that of Experiment 1, the only differences relating to the nature

of the stimuli presentations, as described above. The timing of the stimuli were identical to those of Experiment 1.

Results

The same statistical analyses as used in Experiment 1 were performed. During the training phase, the experimental group participants made correct match-mismatch decisions on 86% of the trials. A comparison of means across the two experiments revealed a significantly higher training performance in Experiment 2, $F(1, 18) = 14.21, p < .01$.

Results for the testing phase revealed that the control group correctly classified 47% of the test sequences while the experimental group correctly classified 63% of the test sequences. An ANOVA (experimental vs. control group) indicated that the main effect of group was significant: $F(1, 18) = 3.15, p < .01$. Single group t-tests revealed that the control group's performance was not significantly different from chance, $t(9) = -1.11, p = .3$, whereas the experimental group's performance was significantly different from chance, $t(9) = 3.03, p < .05$.

The results indicate that the experimental group significantly outperformed the control group. In addition, overall experimental and control group performance at test was very similar to that observed in Experiment 1, suggesting commonalities between tactile and visual sequential learning.

Experiment 3: Auditory Sequential Learning

Experiment 3 assessed sequential learning in the auditory domain. This experiment was identical to Experiments 1 and 2 except that it used sequences of auditory tones. Like the previous experiments, Experiment 3 had an experimental group, undergoing training and testing phases, and a control group, undergoing the testing phase only. Although previous research has found similar statistical learning performance in vision and audition (Fiser & Aslin, 2002), other data suggest that audition excels at sequential processing tasks (Handel & Buffardi, 1969; Sherrick & Cholewiak, 1986); therefore, we might expect to see a difference in auditory compared to visual and tactile sequential learning.

Method

Participants An additional 20 undergraduates (10 in each condition) were recruited from introductory Psychology classes at Cornell University.

Apparatus The apparatus was the same as Experiment 2. The auditory tones were generated using the SoundEdit 16 version 2 software for the Macintosh.

Materials The sequences were identical to those used in the previous experiments except that instead of vibrotactile pulses or flashing black squares, they consisted of musical tones beginning at middle C (1 = C, 2 = D flat, 3 = F, 4 = G flat, and 5 = B).⁵ Each tone lasted 250 ms and was separated by 250 ms. Thus, the sequence 1-2-5-5 consists of a C, then a D flat, and lastly two B's.

Procedure The overall procedure was the same as that of the previous experiments.

Results

During the training phase, the experimental group participants made correct match-mismatch decisions on 96% of the trials. This training performance was significantly higher than that of Experiment 2, $F(1, 18) = 10.20, p < .01$.

Results for the testing phase revealed that the control group correctly classified 44% of the test sequences while the experimental group correctly classified 75% of the test sequences. An ANOVA (experimental vs. control group) indicated that the main effect of group was significant: $F(1, 18) = 7.08, p < .001$. Single group t-tests revealed that the control group's performance was marginally worse than chance, $t(9) = -2.25, p = .051$, indicating that our test stimuli were biased against a positive effect of learning. The experimental group's performance was significantly different from chance, $t(9) = 7.45, p < .001$.

Like the previous experiments, the data indicate that the experimental group significantly outperformed the control group; hence, participants appeared to learn aspects of the statistical structure of the input. In fact, the experimental group test performance appears to be substantially greater compared to those of Experiments 1 and 2 (75% vs. 62% and 63%).

General Discussion

Assessing first the training results, we found that performance was significantly different across all three experiments (audition = 96%; vision = 86%; touch = 74%). Because the training task essentially involves remembering and comparing sequences within pairs, the results may elucidate possible differences between the three modalities in representing and maintaining sequential information (Penney, 1989). It is also possible that these results are due to factors such as differential discriminability or perceptibility of sequence elements in different sensory domains.

⁵ This particular set of notes was used because it avoids familiar melodies.

The testing results for all three experiments are summarized in Figure 2. All three experiments are similar in that the experimental group test performances were significantly different from both chance and their respective control groups. From these results, it appears that participants learned aspects of the adjacent element statistical structure inherent in the training input, allowing them to classify novel stimuli. In this manner, tactile, visual, and auditory sequential learning display commonalities. It is especially interesting to note that sequential learning is not limited to the visual and auditory modalities, but extends to touch as well.

Figure 2: Summary of test results (# of correct responses out of 20).

Despite this overall similarity across modalities, it is also apparent that the Experiment 3 (auditory) results are somewhat different from the other two experiments. Specifically, the auditory experimental group performed better at test as compared to the tactile and visual experimental groups (75% vs. 62% and 63%). This difference is in fact significant [$F(1, 54) = 6.03, p < .05$].⁶ Thus, it appears that in this task, auditory sequential learning was more successful than both tactile and visual learning. While previous research has suggested that audition excels at relatively low-level temporal processing tasks (Mahar et al., 1994; Sherrick & Cholewiak, 1986), our results appear to be the first evidence that such an advantage extends to complex temporal processing, namely statistical/sequential learning. This auditory advantage perhaps is related to the finding that adults process tone sequences by representing relative, as opposed to absolute, pitch (Saffran & Griepentrog, 2001); such a strategy may allow for more efficient encoding of adjacent element statistics.

⁶ This was computed by contrasting the means of the experimental and control groups, as illustrated by the equation: $E3-C3 = .5(E1-C1) + .5(E2-C2)$, where E and C refer to experimental and control group means, respectively.

Conclusion

It has been argued that statistical learning is subserved by a single, domain-general mechanism (e.g., Kirkham et al., 2002). Although a single-mechanism view may be theoretically attractive, our results point toward another possibility: that sequential learning may involve multiple, modality-constrained processes. This idea is supported by a recent multivariate meta-analysis of 35 PET experiments (Lloyd, 2000), which suggested that computations in the different "sensory streams" (i.e., representations of tactile, visual, and auditory information) rely on entirely different cortical areas altogether, at all levels of processing. Additionally, neuroimaging evidence specifically related to sequential learning is consistent with a multiple-mechanism view (see Clegg, DiGirolamo, & Keele, 1998). Thus, we propose that sequential learning is best understood as a functional "suite", composed of multiple, modality-constrained mechanisms. Each mechanism is instantiated in largely non-overlapping brain areas but some degree of interaction is likely to occur between them. We further suggest that each modality-constrained mechanism shares similar computational properties with one another, including the ability to extract adjacent element statistics from incidental exposure to input. However, because each learning mechanism is largely tied to specific sensory areas, each is constrained by the global properties of that sensory system. These properties presumably relate to the types of information that each sensory modality is specialized to process, such as temporal, spatiotemporal, or spatial configurations (Mahar et al., 1994). Our experimental data illustrate one example of such specialization: the auditory system encoded statistical information of temporal input more effectively than did the other senses. Important targets for future research include further substantiating this multiple mechanism view of sequential learning and to discover how such modality-constrained systems might interact with each other, as well as how each relates to human cognition in general. We anticipate that such future research, especially that involving neurophysiological experimentation, will further elucidate the nature of sequential learning by touch, vision, and audition.

Feedback Effects in the Acquisition of a Hierarchical Skill

Andrew Corrigan-Halpern (ahalpe1@uic.edu)

Stellan Ohlsson (stellan@uic.edu)

UIC Department of Psychology, 1007 W. Harrison
Chicago, IL 60607

Abstract

Complex cognitive skills cannot be learned without feedback. There are reasons to believe that positive and negative feedback function differently. For skills that are represented hierarchically, feedback can provide information locally, concerning individual actions, or more globally, referring to higher level goals. A 2-by-2 factorial experiment showed an interaction between type of feedback (positive or negative) and scope of feedback (global or local). Contrary to the wide spread belief in the effectiveness of positive feedback, local negative was most effective. Global negative feedback was least effective. Positive feedback fell between these two conditions and was less affected by scope. The results are discussed in terms of the information content of the feedback.

Introduction

A large part of learning consists of gradually fine-tuning our efforts until we have succeeded in the task at hand. Learners may be able to evaluate progress without aid in simple tasks, but for complex tasks they rely on feedback (Kluger & DeNisi, 1996). For complex tasks, performance will often involve the execution of many goals, each involving the application of component skills (Kotovsky & Simon, 1973).

Many of the studies that employ feedback use it in the service of other research interests and are less concerned with comparing one feedback condition to another. Feedback is used to establish the levels of learning that the purpose of the experiment requires, but is not itself the object of study. Consequently, we know less about the cognitive function of feedback than one might expect. Studies that do focus on the feedback itself report contradictory findings and no current theory can fully explain why feedback is effective.

Some contrary findings may be explained by the fact that studies take one of two approaches, either investigating the informational or the motivational impact of feedback (Kluger & DeNisi, 1996). However, inconsistencies are not eliminated when we limit our survey to one or the other approach. In this article, we focus on the information aspect of feedback.

Background and Rationale

It seems obvious that if feedback is helpful, then more feedback should be more beneficial than less feedback. Many investigations have studied the impact of feedback rate (Salmoni, Schmidt, & Walter, 1984). In some cases, increasing the rate improves performance (Kulik & Kulik, 1988; Salmoni et al., 1984; Schmidt et al., 1989; Thorndike,

1927). In other studies, increasing the feedback rate is found to hinder performance (Bourne, 1957; Bourne & Bundeson, 1963; Schroth, 1997). This indicates that the effect of feedback is strongly mediated by other variables.

We would expect the content of the feedback itself to be one such variable. Studies in social psychology suggest that feedback is less effective when it draws attention to general performance or to self-efficacy and it is most effective when it draws attention to the task itself (Kluger & DeNisi, 1998). Another relevant variable is the type of task the learner is acquiring knowledge about. For complex tasks, feedback might foster more active processing, enhancing performance. For simple tasks, constant feedback may interfere with deeper evaluation, reducing performance. (Schmidt & Wulf, 1997). A third variable that affects the outcome reported in a study is the manner in which feedback is measured. The most effective feedback condition as measured during training might not be the most effective condition as measured by transfer measures (Schmidt, Young, Swinnen & Shapiro, 1989; Schroth, 1997).

In the study reported in this paper, we focus on yet another dimension of feedback: whether it provides information about appropriate, correct and useful actions, which we refer to as *positive feedback*, or whether it provides information about errors and mistakes, which we call *negative feedback*. Empirical work supports the notion that negative and positive feedback have qualitatively different effects (Taylor, 1991).

There is widespread belief that positive feedback is more effective than negative feedback. A simple argument about *information content* supports this belief: When a learner receives information that an action is appropriate, correct or useful, this requires neither change nor interpretation. The straightforward implication is that he or she should repeat that action when a similar situation arises in the future. When a learner receives information that his or her action was an error, he or she merely knows to avoid that particular action in the future, but not which action to perform instead. Positive feedback provides definite information, while negative feedback requires interpretation of the cause of the error and the selection of an alternative action. The interpretation process for negative feedback can be quite complex (Ohlsson, 1996).

The argument from information content is even stronger if we factor in the *scope* of the feedback. Many situations in real life do not provide feedback immediately after every elementary action. The effects of one's behavior might be delayed until after a series of actions has been completed

(Salmoni, Schmidt, & Walter, 1984). We call feedback that refers to a single action as being *local* in scope. Feedback that refers back to a series of actions is *global* in scope. The interpretation problem for global negative feedback is even more difficult than for local feedback. If a series of actions ends in an undesirable outcome, which part of the underlying cognitive skill should be affected by this feedback? If the sequence of actions is controlled by a subgoal, which in turn is dominated by a superordinate goal, which goal or goals should be affected by the negative feedback? During problem solving, a correct higher goal can dominate an incorrect lower goal, and vice versa. In prior work with a simulation model, we have shown that situations can arise in which a hierarchical, feedback driven system fails to learn because a superordinate and correct goal cannot recover from the negative feedback generated by incorrect lower level goals or actions (Corrigan-Halpern & Ohlsson, 2001). Ohlsson & Halpern, 1998). In contrast, global positive feedback does not seem to pose a more complex interpretation problem than local positive feedback. Learning that an entire sequence of actions was correct should be more powerful than receiving similar information about a single action.

However, empirical and theoretical research is not fully in accord with the implications of the argument from information content. Some researchers have indeed found that positive feedback is more effective than negative feedback (Greeno, 1974). However, in other cases, negative feedback was found to produce better performance (Mesch, Farh & Podsakoff, 1994). In prior work using a computer simulation model, we showed that some combinations of learning mechanisms imply that negative feedback will have a stronger impact on learning rate than positive feedback (Ohlsson & Jewett, 1997). The interaction with scope appears not to have been systematically investigated.

Closer scrutiny of the information content argument itself shows that it overlooks potential interactions with some of the factors mentioned above. The difference between practicing a simple task – drill – and solving an unfamiliar problem might be important. During problem solving, many actions are taken tentatively, with little or no rationale. When such an action fortuitously generates positive feedback, the learner only gains knowledge about how to solve that particular problem. To learn something that transfers to a related but different problem, he or she must figure out *why* the action worked. Hence, in this case, positive feedback requires interpretation. On the other hand, when the learner has acquired a rationale for his or her responses, then the positive feedback arrives after learning.

In summary, a straightforward application of the information content argument suggests that positive feedback should be more effective than negative feedback and that the advantage should be greater for large than for small scope, but this argument overlooks potential complicating factors. In the present study, we aimed to increase available information about these issues by

systematically varying both feedback type and feedback scope, and by assessing the outcome during learning, after learning, and with transfer tasks.

Method

Participants. Ninety-four undergraduates participated in return for class credit.

Task. The subjects mastered a version of the sequence extrapolation task studied by, among others, Simon and Kotovsky (1963). The subject is shown a series of letters that follow a specifiable pattern (e.g., MABMCDM ...). Then he or she is asked to extrapolate the pattern to N additional places (EFMGHM...). We used a type of extrapolation problem that incorporated the hierarchical organization typical of the related problems studied by Restle (1970).

To make letter extrapolation into a task with multiple opportunities to receive feedback, we presented the given sequence via several short presentations and asked for a response after each one. The subjects viewed the given sequence for 20 seconds, then attempted to extrapolate it. They were asked to reproduce as much of the pattern as they could, guessing the letters for which they were uncertain. They received feedback on their extrapolation as described in detail below. Then the next trial (20 second study period, plus extrapolation attempt) began. The subjects went through 12 such trials.

To make the problem more difficult, a different sequence of letters was presented on each trial. For example, suppose a subject studied the sequence C A D F F D A C D B E G G E B D. He or she was prompted with the letter M and the correct extrapolation was M K N P P N K M N L O Q Q O L N. On the following trial, he or she saw a new instantiation of the pattern, e.g., F D G I I G D F G E H J J H E G. He or she was again prompted with M and the correct extrapolation was once again M K N P P N K M N L O Q Q O L N. The extrapolation prompt (M), and hence the correct extrapolation, was the same on each trial.

The tasks were presented on a 15 inch computer monitor with help of the PsyScope experimental control software. The given sequences were presented in black letters on a white background. When the 20 second study period ended, the given sequence was erased and the prompt M appeared on the screen to the left of a horizontal row of 15 answer boxes. The subjects gave their answer by clicking on the answer boxes in any order and typing in a letter. When done, they clicked on a 'Done' button, and the next trial commenced.

Design. In a 2-by-2 between-subjects design, we varied feedback with respect to type (positive vs. negative) and scope (local vs. global). *Negative feedback* consisted of the word "wrong" appearing in red text underneath an incorrect response. *Positive feedback* consisted of the word "correct" appearing in green text underneath a correct response. Each subject saw only one type of feedback.

Because feedback is intermittent in most real learning scenarios, we provided feedback probabilistically. A subject in a negative feedback condition received feedback on a random selection of 75% of his or her errors. For the remaining 25% of erroneous responses, plus all his or her correct responses, the subject saw the word "none" in white letters on black background below his or her response. The instructions emphasized that "none" meant that the response was *either* incorrect *or* correct. This feature prevented subjects from inferring that a response that did not receive negative feedback was correct (and vice versa). The presentation of positive feedback was analogous.

By *local feedback* we mean information about the correctness of a single letter. In contrast, *global feedback* referred to the natural chunks of the extrapolated sequence. Consider the given sequence CADFFDACDBEGGEBD. It consists of two parts, CADFFDAC and DBEGGEBD, which have the same structure but are separated by one position in the alphabet. The first part consists in turn of two subparts, CADF and FDAC, which are mirror images of each other; similarly for DBEG GEBD. Hence, the correct extrapolation MKNPPNKMNLOQQOLN consists of the four chunks MKNP, PNKM, NLOQ, and QOLN. In the global conditions, feedback was given with respect to these chunks by drawing a line underneath each group of four answer boxes; the word "correct", "wrong" or "none" appeared under the center of that line. The instructions emphasized that the feedback referred to the entire group of four letters. Thus, negative feedback meant that *at least one* of the responses in that group was wrong. In order to be get global positive feedback, all the responses in a chunk had to be correct.

In both the local and global conditions, the feedback remained on the screen for 45 seconds before the next trial commenced.

Procedure. The experiment began with an *Instruction* stage, in which subjects were given general information about the experiment. They were also taught the three relevant pattern construction operations (displace a letter or a group of letters one position forwards or backwards in the alphabet; repeat a letter or group of letters, and extend a sequence with its own reversal) with both verbal descriptions and examples. In the *Training* stage, the subjects went through twelve trials with respect to the target problem, as described above. In the *Assessment* stage, the subject solved the target problem twice without prior presentation of the given sequence and without feedback. That is, the prompt letter M appeared together with the answer boxes, and the subject attempted to fill them in; then M appeared again and the subject filled in the answer boxes once more. In the *Transfer* stage, the subject tried to solve a letter sequence problem with the same pattern as the pattern in the target problem. However, the prompt letter was T instead of M. In this case, the correct extrapolation consisted of a completely different sequence of letters. No feedback was given on the transfer problem.

Results

Analysis of Learning Stage

A Mixed ANOVA was performed to assess performance during the learning stage. All 12 Training trials were entered as a within-subjects factor. Feedback Scope (local or global) and feedback Type (positive or negative) were entered as between-subjects factor. The dependent measure was the number of letters correct per trial. There was a significant learning effect as shown in Figure 1, $F(990, 11) = 42.21, p < .001$. There was no effect of feedback Scope, $F(90, 1) = 1.33, p > .05$. There was no effect of feedback Type, $F(90, 1) = 0.31, p > .05$. There was an interaction between Scope and Type, $F(90, 1) = 8.45, p = .005$, indicating that the effectiveness of either feedback type is mediated by scope.

Figure 1. Performance on the training trials.

We hoped that by training subjects on the three construction rules, and by providing problems with a chunking structure, we would maximize the likelihood that they would represent the pattern hierarchically. To test whether this manipulation worked, we examined the inter response time for each position.

We computed solution times for each of the positions of the pattern. There was no time for the first letter of the pattern since this was given to subjects in the form of the prompt "M". We analyzed the last four trials of training, so that we could capture the final product of learning, the point where subjects would have come to represent the pattern hierarchically. Four subjects were removed from the analysis because they omitted responses on one or more of the trials. Figure 2 shows the result.

Subjects spent the longest times at the beginning of the pattern. The first three responses "K" "N" and "P" correspond to the first chunk. The high latency for the first "K" probably reflected initial time planning to reproduce the pattern. The next four positions (5-8) correspond to the second chunk, "PNKM". Since subjects could reproduce these letters by reflecting the first chunk, response times were much quicker and there was a trend for these positions to form a horizontal line. The next chunk "NLOQ" involves the translation of the first chunk by one letter in the alphabet. This required more effort as indicated by the increase in latency from position 8 to position 9. The last chunk, "QOLN", could also be completed by reflection. Latencies match those of the second chunk and the horizontal trend is again present.

Figure 2. Time to complete each position averaged across the last 4 learning trials.

Analysis of Assessment and Transfer Stages

A mixed within-subjects ANOVA was performed for the Assessment trials. Both trials of the Assessment stage were entered as within-subjects measure. Type and Scope were entered as between-subjects measures. The dependent measure was the number of letters correct per trial.

There was no effect of feedback Type, $F(90, 1) = 0.10$, $p > .05$ and no effect of feedback Scope $F(90, 1) = 3.23$, $p > .05$. The interaction between Type and Scope was once again significant, $F(90, 1) = 7.70$, $p < .01$, indicating that the effect of feedback type depends on scope. There were no effects involving the repeated measure. Figure 3 shows the results for the Assessment trials.

The two Transfer trials were entered as a within-subjects measure in an ANOVA. Feedback Type and Scope were entered as between-subjects measures. The dependent

measure was the number of letters correct per trial. There was neither an effect of Type nor of Scope, $F(90, 1) = 0.05$, $F(90, 0) = 2.15$, $p > .05$. The interaction between Type and Scope was once again significant, $F(90, 1) = 7.58$, $p < .01$. Figure 4 shows the results for the Transfer trials.

Figure 3. Accuracy for the two Assessment trials.

Figure 4. Accuracy for the two Transfer trials.

In summary, we first showed that learning occurred during the Training stage of the experiment and we verified that subjects were representing the pattern hierarchically. We showed that during all of the stages of the experiment there was an interaction between Scope and Type. This interaction is driven by the fact that negative feedback is maximized when provided locally, $F(90, 1) = 9.88, p < .005$, while for positive feedback, there is no significant effect of Scope, $F(90, 1) = 1.36, p > .05$.

Discussion

We presented data to show an interaction between feedback Type and feedback Scope. Local negative feedback was the most effective condition, while global negative feedback was the least effective one. Positive feedback fell between these two in effectiveness. Performance was similar for the two positive feedback conditions, suggesting that for this type of feedback Scope plays a limited role. This exact pattern of outcomes recurred during training (see Figure 1), in the assessment tasks (see Figure 3), and in the transfer tasks (see Figure 4).

This is not the pattern that is predicted by a straightforward formulation of the information content argument, since it predicts that the two positive feedback conditions should be best. According to the latter, negative feedback should provide less information regardless of scope, but this is not what we found. Furthermore, it is unclear what the information content argument predicts with respect to a transfer task in which the exact solution acquired during training is no longer sufficient. Nevertheless, the same pattern was observed in the transfer tasks.

We propose an alternative to the information content view, one where the informational content plays a role, but where it is not the only factor. In this study, negative local feedback was superior to negative global. Since negative local feedback provides direct information concerning individual responses, it is easier to interpret and hence can more directly be used to change subsequent responses. This explains why local negative feedback was more effective than global, but it does not explain our findings with respect to positive feedback.

Positive feedback applies in either of two cases. During problem solving, responses are sometimes made tentatively, without a rationale or reason. In the case of such fortuitously correct responses, positive feedback requires no less interpretation than negative feedback: *why* was the response correct? When the rationale has been worked out, the feedback arrives after learning has already occurred. The argument from information content ignores the dynamics of learning. Negative feedback is naturally received before learning occurs, and hence can influence and support learning. If the learner already knows how to generate a

correct answer, the information in the resulting positive feedback is not novel and hence might not contribute strongly to learning.

This study has multiple limitations. The learning phase was short, only twelve trials. The feedback messages were limited to "correct" versus "incorrect" with none of the explanatory content that would be likely to accompany a feedback message in a realistic instructional situations (but not always in realistic situations where the feedback is 'delivered' by physical reality itself, e.g., in the form of a malfunctioning device). The transfer tasks were only moderately distant from the training tasks. The generalisability of the interaction between scope and type of feedback cannot be determined at this time. Future work will address these limitations.

What emerged clearly in this course of this study is that, contrary to the wide spread impression that feedback during problem solving practice is a topic that has been studied to death, we do not, in fact, know very much about the function of feedback. In particular, we do not understand the space of relevant parameters, and we do not know how currently identified parameters interact. It is plausible that the contradictory findings mentioned in the introduction are due to aggregation over overlooked interactions. A systematic experimental attack on the determinants of feedback effectiveness is warranted.

Investigating creative language: People's choice of words in the production of novel noun-noun compounds.

Fintan Costello (fintan@compapp.dcu.ie)
School of Computer Applications, Dublin City University,
Glasnevin, Dublin 9, Ireland.

Abstract

The production of novel noun-noun compounds is a prime example of everyday linguistic creativity. What cognitive processes guide people's choice of words when they make up a new noun-noun compound? An experiment examined people's production of noun-noun compounds as names for novel objects. The results showed that people's choice of words in these novel compounds was influenced by the diagnosticity of properties in those objects. By contrast, people's choice of words did not seem to be influenced by the communicative precision of the resulting compounds. These results suggest that, in constructing novel compounds, people are guided by conceptual representation rather than communicative task.

Introduction

The production of noun-noun compounds is a prime example of everyday linguistic creativity. Compounds such as *soccer mom* (a middle-class suburban mother) or *alpha geek* (the person in a workplace who knows most about computers) convey a lot of information in a concise and inventive way. How do people produce novel compounds such as these? What cognitive processes guide people's choice of words when they make up a new noun-noun compound? There has been much recent research on the cognitive processes of conceptual combination, which allow people to understand novel noun-noun compounds by combining their constituent words in meaningful ways (Costello & Keane, 2000, 2001; Gagné & Shoben, 1997; Hampton, 1987; Murphy, 1988; Wisniewski & Gentner, 1991). There has also been much work on the situations in which noun-noun compound production occurs, especially in child language (asking whether children create compounds to fill gaps in their lexicon, to mark contrasts, or to allow more precise communication; see Clark, 1987, Clark & Berman, 1984, Windsor, 1993). However, there has been little research on the specific cognitive processes involved in people's creation of novel noun-noun compounds. This paper attempts to address this gap.

This paper describes an experiment examining people's choice of words in novel noun-noun compounds. In this experiment participants are given a description of a novel object and asked to make up a noun-noun compound as a name for that object. The experiment examined the influence of property diagnosticity on people's compound production. Diagnostic properties for a concept are those which serve to identify members of that concept: a diagnostic property is one that most members of a concept have, but most non-members do not have. Previous research has shown that property diagnosticity is important in people's interpretation of compound phrases (Costello & Keane, 2001). In the current experiment, the novel object descriptions presented to participants are controlled for diagnosticity: some containing diagnostic properties for a given concept, others containing

non-diagnostic properties. If diagnosticity also plays a role in compound production, then there should be a relationship between the diagnosticity of properties in a novel object description, and people's choice of words when producing compound names for that object.

The current experiment uses materials derived from Costello & Keane's (2001) study of diagnosticity in compound phrase interpretation. The first part of this paper describes this earlier study. The second part describes the current experiment examining the production of novel compounds. To foreshadow the results, this experiment found that diagnosticity was an accurate predictor of compound production: in the experiment the more diagnostic the property in an object description was for a given word, the more likely that word was to be used in generating a compound to name that object. An alternative factor, that of communicative precision (Clark, 1987, 1990), was not a reliable predictor of compound production. The final part of the paper links these findings to other research on concept combination and compound production.

Diagnosticity in the Interpretation of Noun-Noun Compounds

How are people able to understand and grasp the meaning of a noun-noun compound which they have never seen before? When confronted with a novel noun-noun compound, people interpret that compound by combining the compound's modifier concept (the first word in the compound) with the compound's head concept (the second word). People can combine these two parts in a variety of different ways. Three main combination types have been recognised: conjunctive, relational, and property-transfer interpretations (Hampton, 1987; Murphy, 1988; Wisniewski & Gentner, 1991). In conjunctive interpretations people produce a combined concept that is an instance of both concepts being combined (e.g., "a *pet bird* is a bird which is also a pet"). In relational interpretations people assert a relation between the two concepts being combined ("an *apartment dog* is a small dog which lives in city apartments"). In property-transfer interpretations people create a new combined concept by transferring a property from the modifier concept to the head. For example, the compound "elephant pig" might be interpreted as "an *elephant pig* is a pig that has tusks": the transfer of a property from the modifier concept ("elephant") to the head concept ("pig"). These property-transfer combinations have been the focus of much recent research (Costello & Keane, 2001; Gagné, 2000; Wisniewski & Love, 1998). This focus in this paper is on property-transfer combinations.

Costello & Keane (2001) describe an experiment examining people's interpretation of property-transfer combinations. The

experiment was designed to test two differing predictions about these property-transfer combinations. One prediction was that the transferred property would be a structurally aligned difference between the modifier and head concepts; that is, a property in the modifier concept that structurally corresponds to a different property in the head (Wisniewski, 1996). The competing prediction was that the transferred property would be a diagnostic property of the modifier (source) concept; that is, a property that helps identify members of that concept and distinguish it from other concepts (Tversky, 1977; Costello & Keane, 2000). In this experiment, participants were shown 16 novel compound phrases, with 4 different property-transfer interpretations as possible meanings for each phrase. Using two pre-tests, the 4 interpretations for each compound were controlled and crossed for structural alignment and diagnosticity. For example, for the phrase "elephant pig" the 4 interpretations were

Elephant pigs are

- pigs that are big (diagnostic, aligned)
- pigs that are grey (non-diagnostic, aligned)
- pigs that have tusks (diagnostic, non-aligned)
- pigs that are an endangered species (non-diagnostic, non-aligned)

Participants were asked to judge how good or bad they thought each property-transfer interpretation was as a meaning for the compound phrase in question, and to rate the acceptability of each interpretation on a scale going from -3 to +3.

The results of this experiment showed that people's interpretation of property-transfer compound phrases was strongly influenced by the diagnosticity of the transferred property for the modifier concept in the combination. People reliably rated interpretations using diagnostic properties as acceptable, and those using non-diagnostic properties as unacceptable. There was a significant correlation between the acceptability of interpretations and the rated diagnosticity of the properties they contained. Structural alignment had no influence on people's interpretation acceptability ratings in the experiment. In a subsequent test participants were shown the same phrases and simply asked to write down their own interpretations. Again, diagnosticity, but not structural alignment, influenced people's interpretation of the phrases.

Costello & Keane's (2001) materials provide the basis for the current experiment on role of diagnosticity in people's production of novel compound phrases. Costello & Keane's materials were constructed as follows. First, 16 participants in a property-generation task produced lists of properties for the modifier and head concepts of the compounds used in the experiment. For the modifier concept in each compound, 4 frequently-listed properties were selected. The diagnosticity of these 4 properties was then obtained in a diagnosticity-rating task. Another set of participants were shown the selected properties, each property being paired with the modifier concept of the relevant compound. Participants were asked to imagine they were playing the game in which they had to help the other player to guess the concept shown. They were asked to rate how helpful each property would be in helping their partner identify the concept in question. For example, to assess the diagnosticity of properties for the

concept "elephant", participants were asked to rate how helpful each of properties:

- are big
- are grey
- have tusks
- are an endangered species

would be in allowing their partner in the game to identify the concept "elephant". Participants rated the helpfulness of the properties on a 7 point scale going from -3 (not at all helpful) to +3 (very helpful). Diagnostic properties were those whose average rating was above 0 on this 7-point scale. Two diagnostic and two non-diagnostic properties were obtained for each modifier concept, and these properties were used to construct the 4 interpretations for the compound phrase in question. In the main experiment, participants rated the acceptability of these interpretations for those compound phrases. The next section describes how these materials were used to investigate the role of diagnosticity in the production of compound phrases.

Diagnosticity in the Production of Noun-Noun Compounds

The previous section described an experiment showing that, in interpreting compound phrases, the property diagnosticity plays an important part. Is diagnosticity also important when people are producing, rather than interpreting, compound phrases? This section describes an experiment addressing this question.

In this compound production experiment, participants were shown descriptions of unusual objects and asked to generate compound names for those objects. The object descriptions used were selected from the interpretations used in the comprehension study. Each of the 16 phrases in the earlier experiment had 4 object descriptions as interpretations, two using diagnostic properties and two using non-diagnostic properties. In the current experiment one diagnostic and one non-diagnostic object description was selected for each phrase. Participants were given the object descriptions alone (and not given the compound phrases). They were then be asked to generate a two-word noun-noun phrase to name that object. For example, some participants were given the object description

- "a special type of pig that has tusks"

and asked to write down a two-word noun-noun phrase to name that special type of pig. Other participants were given the object description

- "special type of pig that is grey",

and asked to come up with a noun-noun phrase for that object. The question of interest was whether participants would produce the phrase which corresponded to that object in the earlier experiment; that is, whether participants would produce the phrase "elephant pig" as a name for "pigs that have tusks". Notice that in the object description the head word for the phrase in question is already given (participants already know that the object described is a type of pig, and so would most

likely use that word as the head of whatever phrase they produce). The focus of analysis in the experiment is therefore on people's choice of modifier word for the phrases they generate. Will people be more likely to produce the expected modifier for object descriptions containing diagnostic properties ("pigs that have tusks") than for those containing non-diagnostic properties ("pigs that are grey")?

Method

Participants. The participants were 18 Dublin City University undergraduates who took part for course credit.

Materials. The materials were 16 sets of object descriptions. Each set contained two object descriptions both of which had the same target phrase consisting of a modifier and a head. (Appendix A shows all 16 sets of object descriptions and target phrases). One object description contained a diagnostic property for the modifier concept in that target phrase; the other object description contained a non-diagnostic property for that concept. Participants in the experiment saw one object description from each set. Participants did not see the modifier concept for the target phrase for that set. The factor of interest was whether participants would produce a phrase containing the target modifier concept. Object descriptions were taken from the materials of Costello & Keane's (2001) experiment on compound phrase comprehension. The framing phrase "a special type of..." was added to each object description (so that, for example, participants were asked to produce a noun-noun compound to name "a special type of pig that has tusks").

Design. All participants saw 16 object descriptions, one from each of the 16 object-description sets. Participants were randomly divided into two groups. The first group of participants obtained the diagnostic object descriptions from one half of the object-description sets and the non-diagnostic descriptions from the other half. The second group of participants obtained non-diagnostic object descriptions from the first half of the object-description sets and the diagnostic object descriptions from the other half.

Procedure. Each participant received a booklet consisting of an instruction sheet followed by 16 object-description sheets in random order. Each object description sheet had an object description at the top of the page, and three slots in which participants were asked to write down three noun-noun compound names for the object described at the top of the page. Each slot provided space for a modifier and a head concept. Participants had 40 minutes to complete the task.

The instruction sheet explained to participants that they would be asked to read a set of object descriptions and to respond by writing down some noun-noun phrases which they thought would be good names for the objects described. Four examples of familiar noun-noun phrases were given, to illustrate the type of response required. These examples were marked with a tick, to show that they were the correct type of response (see Table 1). These examples involved various different relationships between the nouns in the phrase.

A pre-test showed that, when asked to produce compound phrases as names for object descriptions, participants

Table 1. Examples of correct responses in instruction sheet.

Special type of thing	Correct compound
a special bed with hot lightbulbs above it, giving the user a tan.	a "sun bed" ✓
a special bike with strong rugged tyres and frame.	a "mountain bike" ✓
a special padded glove which protects against heat.	an "oven glove" ✓
a special lamp containing moving bubbles of hot, coloured oil.	a "lava lamp" ✓

sometimes simply reproduced a word from the description rather than coming up with a new noun-noun phrase (producing the compound name "tusked pig" for the object description "a special type of pig that has tusks", for example). To avoid uninteresting responses of this type, instruction sheet stressed that, in producing a compound name for an object, participants should not simply reproduce the words used in the description of that object. Participants were shown four examples of compounds which simply reproduced terms from an object description (Table 2, below). These were marked by crosses to show they were incorrect responses.

Results

The noun-noun phrases produced by participants for the object descriptions were analysed by counting, for each object description, the number of participants who produced that description's target phrase as a name for that object description. For the object description "a special type of pig that has tusks", for example, this would mean counting how many participants produced the target phrase "elephant pig" for that object description. Variations of the target phrase were allowed if they clearly included the target modifier; for example, if a participant produced a blending such as "ele-pig" for "a special type of pig that has tusks", that would be taken as an occurrence of the target phrase.

For each target phrase there were two object descriptions; one using a diagnostic property of the modifier concept, the other using a non-diagnostic property of the modifier. For each target phrase, one group of 9 participants saw one object description, the other group saw the other object description; thus each object description was seen by 9 participants. For the object descriptions containing diagnostic properties of the modifier concept, the target phrase was produced by 3 out of 9 participants, on average. For the non-diagnostic object descriptions, the target phrase was never produced.

Table 2. Examples of incorrect responses in instruction sheet.

Special type of thing	Incorrect compound
a special bed with hot lightbulbs above it, giving the user a tan.	a "lightbulb bed" ✗
a special bike with strong rugged tyres and frame.	a "rugged bike" ✗
a special padded glove which protects against heat.	a "protective glove" ✗
a special lamp containing moving bubbles of hot, coloured oil.	a "coloured lamp" ✗

Figure 1. Probability of target phrase production for the 16 diagnostic-property object descriptions, and diagnosticity of properties for modifier in target phrase (diagnosticity mapped to probability scale).

Results: diagnosticity. The previous analysis showed that participants were clearly more likely to produce the target phrase for descriptions with diagnostic properties than for descriptions with non-diagnostic properties. A more detailed examination of the role of diagnosticity in compound phrase production was performed by analysing the relationship between the diagnosticity of properties in descriptions and the rate of target phrase production for those descriptions. This analysis was carried out for diagnostic-property descriptions only (the only descriptions for which the target phrase was produced). There was a significant correlation between the average rated diagnosticity of properties in these descriptions for the modifier concept (obtained from the pre-test for Costello & Keane's (2001) experiment), and the probability of target phrase production for those descriptions. The more diagnostic the property in an object description was for the modifier, the more frequently participants produced the target phrase ($r = 0.81$, $p < 0.001$, $\%var = 0.66$). Figure 1 shows a graph of probability of target phrase production versus average property diagnosticity for the 16 diagnostic object descriptions. (In this graph property diagnosticity is mapped from its original rating scale of -3 to +3 onto the 0 to 1 interval on which probability of target phrase production is shown).

This result suggests that the production of novel noun-noun phrases for property-based object descriptions can be predicted from the diagnosticity of properties in those object descriptions. It might be argued, however, that the target phrase production in the experiment was not influenced by property diagnosticity per se, but by a more general association between the properties and concepts in question. For example, it could be that the phrase *elephant pig* was produced frequently for the object description "a special type of pig with tusks", not because having tusks is specifically diagnostic in identifying the concept *elephant*, but because there is a general association between elephants and tusks.

Figure 2. Probability of target phrase production for the 16 diagnostic-property object descriptions, and acceptability of descriptions as interpretations for phrases (acceptability mapped to probability scale).

To address this possibility a general measure of association between concepts and properties was obtained from Costello & Keane's (2001) original property-generation task. In that task, 16 participants listed properties for the concepts used in the experiment. For each property and concept, the number of participants who listed that property as belonging to that concept was obtained. This number was taken to be a measure of the general association between the property and the concept. The correlation between this property-concept association and the rate of target-phrase production did not reach significance ($r = 0.41$, $p > .1$, $\%var = 0.17$). This suggests that it is diagnosticity specifically, rather than a more general association between properties and concepts, that is important for compound production.

Results: Communicative accuracy. In addition to examining the role of diagnosticity in compound phrase production, the current experiment allows us to examine the role of communicative precision in people's production of compound phrases. One view of compound production is that people produce novel compounds to allow them to precisely communicate their intended meaning to the listener (Clark, 1987, 1990; Clark & Berman, 1984). In this view, compound production is a listener-centered process: a person producing a compound as a name for a given object will choose a compound that the listener would easily interpret as referring to that object. If communicative precision is important in compound production, there should be a relationship between the rate at which people produce a given compound phrase as name for a particular object, and the degree to which people, when given that compound phrase, describe that object as the correct interpretation for the phrase.

The role of communicative precision in compound phrase production was analysed by comparing the rate at which people produced the target phrase for the given object descriptions in the current experiment against the degree to

which participants in Costello & Keane's (2001) study rated those object descriptions as good interpretations for those phrases. The correlation between the phrase production for a given description and description acceptability as an interpretation for that phrase was not significant ($r = 0.1$, $p > .1$, $\%var = 0.01$). Figure 2 shows a graph of the rated description acceptability as interpretation and target phrase production. This finding of no relation between target phrase production and interpretation acceptability casts some doubt on the role of communicative precision in compound phrase production. This finding is in line with other results (e.g. Windsor, 1993; Elbers, 1988) which also call into question the communicative precision view of compound production.

Conclusion

This paper has examined people's production of novel noun-noun compounds. Compound production is quite a creative linguistic task, with compounds often conveying a lot of information in an inventive way (as in the original *soccer mom* and *alpha geek* examples). The experiment reported here found that compound production is influenced by the diagnosticity of properties for concepts in compounds, but not by the communicative precision of those compounds. This is in line with other findings (Windsor, 1993; Eberts, 1988), suggesting that people's production of novel compounds is influenced more by their conceptual representations than by the communicative task that they are carrying out.

Why should diagnosticity play a role in people's novel compound production? Diagnostic properties are properties which help identify items and classify them as members of particular categories. Perhaps diagnosticity is important in compound production because in compound production the choice of words depends on judgements of category membership. According to this suggestion, when producing the phrase "elephant pig" as a name for the object description "a special type of pig with tusks", people use the diagnostic property "tusks" to classify the object described as to some extent falling into the category "elephant", thus allowing the modifier "elephant" to be used in forming the phrase. This is in line with Costello & Keane's (2000, 2001) proposal on the role of diagnosticity in compound interpretation. According to this proposal, when people interpret the phrase "elephant pig" as "a pig with tusks" they are asserting the diagnostic property "tusks" because it allows the newly described object to be classified under the category "elephant", hence justifying the compound (see Costello & Keane, 2000, for a computational model of implementing this approach).

How do the results reported here fit with other work on language production? The main stream of research on language production tends to use a "picture-naming" task to focus on people's production of words in response to a single concept. In this task people are presented with a picture of a single concrete object (e.g. a picture of a rabbit) and are asked to name that object. Models of language production in this framework typically have 5 stages: (i) Preliminary Analysis,

(ii) Feature Recognition, (iii) Categorisation, (iv) Lexical Access, and (v) Decision (Bock & Griffin, 2000). The suggestion that diagnosticity is important in compound production because it related to judgements of category membership, fits nicely into the third Categorisation stage in this framework. Indeed, the findings of the current experiment suggest that property diagnosticity may play an important role in the Categorisation stage in this language production framework.

APPENDIX 1. Object descriptions and target phrases from Experiment

Description Set	Object description		Target phrase (modifier head)
	Property is diagnostic for modifier	Property is not diagnostic for modifier	
1	A special type of chair that has blankets	A special type of chair that has wheels	Bed chair
2	A special type of moth that stings	A special type of moth that fertilises plants	Bumblebee moth
3	A special type of oak that stores water	A special type of oak that is completely green	Cactus oak
4	A special type of pig that has tusks	A special type of pig that is grey	Elephant pig
5	A special type of beetle that jumps	A special type of beetle that eats insects	Frog beetle
6	A special type of antelope that has a long neck	A special type of antelope that has a long tongue	Giraffe antelope
7	A special type of airplane that has horizontal rotors	A special type of airplane that is maneuverable	Helicopter airplane
8	A special type of monkey that has a pouch to carry young	A special type of monkey that doesn't climb trees	Kangaroo monkey
9	A special type of lobster that has eight limbs	A special type of lobster found in warm water:	Octopus lobster
10	A special type of robin that can talk	A special type of robin that can be a pet	Parrot robin
11	A special type of horse that has a horn	A special type of horse that is very dangerous	Rhinoceros horse
12	A special type of squirrel that smells bad	A special type of squirrel that lives on the ground	Skunk squirrel
13	A special type of spider that has a shell	A special type of spider that eats plants	Snail spider
14	A special type of iguana that slithers	A special type of iguana that is used to make handbags	Snake iguana
15	A special type of slug that is poisonous	A special type of slug that is fast	Viper slug
16	A special type of seal that has a blowhole	A special type of seal that is an endangered species	Whale seal

Do Expression and Identity Need Separate Representations?

Abstract

Recent work has shown that expression recognition shows holistic processing effects much like face recognition (Calder et al., *ress*). We extend our previous model of facial expression recognition (Dailey et al., 2000) to account for these results. We show that our model, with small modifications to the training procedure, can account for the systematic biases between upper and lower facial expression recognition, and the holistic/configural processing effect. Finally, we show that results that seem to support the idea that separate representations are necessary for emotion and identity processing can be accounted for by a single representation model. This latter effect is demonstrated in subjects by constructing chimeric faces by taking the top half of one face and the bottom half of another.

Background

In recent years a consensus has emerged that face processing is "holistic" in nature (Tanaka and Farah, 1993; Farah et al., 1998). Here "holistic" means "configural": that is, there is an effect of the whole in recognition of the parts of a face. One way to show this is to construct composite faces by combining the upper and lower halves of different faces. If the subject's task is to recognize the identity of the upper half of the face, there is interference if the lower half of the face is from a different person. However, if the lower half of the face is misaligned with the upper half, there is no difference in subjects' responses when the lower half is the same person or a different person (Young et al., 1987).

Recently, it has been shown that this effect extends to facial expression recognition (Calder et al., *ress*). Calder et al. first replicate a well-known effect that certain expressions are more easily recognized from their top or bottom halves. A summary of the data is shown in Table 1. Based on this data, Calder et al. constructed composite faces from the same subject using a top-biased emotion in the top half and a bottom-biased emotion in the bottom half. When subjects were asked to identify the emotion in one half, their reaction times were slower when the two halves were aligned versus when they were misaligned.

In further experiments, Calder et al. present data that they interpret as showing that there must be separate representations for facial identity and facial expression processing. The experiment in this case was to show several kinds of composite images to the subjects, and to give them two tasks: identity judgements (after training on the identities of the subjects), and expression judgements. There were three kinds of composite images: 1) same identity, different emotion; 2) different identity, same emotion; and 3) different identity, different emotion. Consider the case of identity judgements. The subjects are asked to judge the identity of the subject in the bottom half of the image. If the top of the image is the same subject, but a different emotion, the reaction times are faster than if the top half of the image is a different subject. This is expected based on the above results on configural processing. However, when the top was a different subject, their reaction times did not differ between the case where the expression of the different subject was the same or different. The interpretation is that identity processing is not affected by affect processing. Identical results in the emotion identification task support the idea that expression processing is not affected by identity processing. The conclusion that two representations must therefore be in play makes intuitive sense, but should be tested in a model. In the following, we show that a single representation suffices to obtain these results.

The Model

We performed three experiments that paralleled as closely as possible three of the experiments reported in (Calder et al., *ress*). In each experiment, we used the same images from the Pictures of Facial Affect (POFA) dataset (Ekman and Friesen, 1976), although normalized as described below. Also, we constructed our own versions of Calder's hand-constructed split images. All experiments used a similar model and data. The details of these experiments are described in this section.

Classification Model

In all experiments, our classification model employs image filtering, principal components analysis

Expression	Human Top	Human Bottom	Net Top	Net Bottom
Happy	0.20 (.09)	0.01 (.01)	0.40	0.00
Sad	0.19 (.05)	0.34 (.08)	0.28	0.40
Afraid	0.33 (.08)	0.56 (.09)	0.28	0.70
Angry	0.28 (.06)	0.49 (.09)	0.29	0.65
Surprised	0.06 (.21)	0.33 (.07)	0.00	0.21
Disgusted	0.62 (.10)	0.04 (.14)	0.20	0.00

Table 1: Fraction of test examples incorrectly identified for each expression. The Human Top and Human Bottom results correspond to the results reported for expression recognition by (Calder et al., 1996). The Net Top and Net Bottom results correspond to the results achieved by our classification model. The number in parentheses is the standard error for the humans.

(PCA), and a single-layer neural network to classify the expression and identity of an input pixel image of an actor posing an expression (Dailey et al., 2000).

Preprocessing of these images begins by aligning the images so that the eyes and mouth of all images are in the same location, then cropping the images to eliminate the background. After each image is aligned, it is convolved with a grid of two-dimensional Gabor jets. Each jet is composed of 40 Gabor filters of five different sizes and eight different orientations. Each jet is centered on a pixel of the aligned image. This image filtering was chosen because it is similar to filtering done in the striate cortex of cats and has previously been shown to improve expression recognition in neural networks (Dailey et al., 2000). Applying Gabor filters to a sub-sampled 240×292 pixel image results in a 40,600 component vector. These vectors are then z-scored (transformed to 0 mean, unit std. dev.) on an individual filter basis, resulting in the Gabor pattern.

As our experiments required a method of directing the classification model's attention to just one half (bottom or top) of the face stimulus, the other half of the face stimulus is attenuated. Each component in the half of the Gabor pattern to be attenuated is multiplied by 0.125. The factor 0.125 was chosen after comparing the results of attenuating by different fractions. An attenuation factor of 0.125 resulted in the error of the model's recognition of expression in half face training data (described below) most closely resembling the error of the human's recognition of expression in half face images. However, we found little variance in the model's error with attenuation factors between 0.5 and 0.125. We define a Gabor filter as being within the half the image to be attenuated if the pixel it is centered on is in that half, or if it is within two times the standard deviation of the Gaussian of the Gabor filter. This way, even filters in the attended half will be attenuated if their receptive field overlaps the other half of the image.

50 principal components of each Gabor pattern are extracted from the training data. These are also

Figure 1: Whole and Half Face Training Data: (a) Aligned and cropped pixel image; (b) Pixels corresponding to the top half; (c) Pixels corresponding to the bottom half.

z-scored. Finally, a soft-maxed single-layer neural network is trained using the cross-entropy error criterion.

Training Data

All stimuli are derived from pixel images from the POFA database. This data set includes images of 14 actors posing 6 expressions: happiness, sadness, fear, anger, surprise, and disgust.

In all experiments, the principal components of the Gabor patterns are extracted from whole face and half face Gabor patterns, and the neural network is trained upon those. We assume that during the learning of the emotions, subjects also attend to just one half of the face at different times. We can think of this as either an attentional process or as a crude simulation of eye movements. In addition, splitting the images between the top half and bottom half, as defined by Calder, resulted in the top half of the image being smaller in area than the bottom half of the image. Extracting principal components while attenuating one half of the image allowed more equal representation of each half in the principal components. Whole face Gabor patterns are created by convolving the original pixel image with the Gabor filters, as described above, then z-scoring these patterns. Half face Gabor patterns are created in a similar manner: the original pixel image is convolved with the Gabor filters and z-scored, then one half of the pattern is attenuated to a fraction of 0.125. Thus, when creating a top half face Gabor

pattern, components corresponding to the bottom half of the face are multiplied by the fraction 0.125. An alternative method would have been to start with a pixel image of just one half of the face, and then convolve the image with Gabor filters. We did not do this because the Gabor filters would have given a strong response at the edge in the image between the zeroed half and the non-zeroed half, and we were concerned that this signal might confuse the network (this may have been an unnecessary worry). An example of an aligned and cropped pixel image and bottom and top half images are shown in Figure 1.

Experiments

Experiment 1

The goal of the first experiment was to determine whether our network gave the same results as Calder et al.'s subjects in terms of which expressions are top-biased and which are bottom-biased. An expression is *top-biased* if it is more accurately identified by our model from the top half of the face than the bottom. An expression is *bottom-biased* if the opposite is true. Calder et al. used 10 of the POFA actors for this experiment. We used the same 10 actors.

The general procedure for this experiment was to classify half face examples using the classification model described above, then compare the classification error for top and bottom test half face examples for each expression. We used "hold one actor out" cross validation, so we trained on nine and tested on the tenth. Each of these were repeated ten times using different initial random weights. The test half-face examples classified by the network are the result of convolving a whole face image with the Gabor filters, z-scoring, attenuating one half using the multiplier 0.0 (thus there is no output from that half), and projecting onto the principal components. Training is stopped when error on the training set most closely corresponds to the human confusion matrix reported by Ekman.

Results: The average results of classifying each test example 10 times are shown in Table 1. The network responses do not vary much over networks. These results show that for our classification model, happy and disgusted are bottom-biased while sad, afraid, angry and surprised are top-biased. These results are very similar to the human results: happy and disgusted are bottom-biased and sad, afraid, and angry are top-biased. The only difference is that our classification model finds surprised to be top-biased while the human results find surprised to be unbiased, due to subject variance. In addition, large differences between the network's classification error fractions of the top- and bottom-half stimuli correspond to large differences between humans' classification error fractions of the top and bottom-half images.

Experiment 2

The goal of the second experiment was to determine if incorrect configural information disrupts the model's expression recognition. This involves comparing the model's accuracy on identifying the expression in one half of two different types of stimuli: composite and noncomposite. A composite example is the result of aligning the top half of one face with the bottom half of another (Figure 2(a)). A noncomposite example is the result of misaligning the top half of one face with the bottom half of another. When performance degrades on composite faces compared to non-composites, this is taken to be an indicator of configural processing (Young et al., 1987). That is, when the two halves are aligned, subjects are unable to ignore the information in the other half of the face, even though they are judging only one half.

In this experiment, both halves of the composite and noncomposite examples correspond to the same actor but different expressions. In Calder et al.'s experiment, reaction times were slower for composite images than for non-composite. Composite images are created by aligning the bottom half of one happy, surprised, or disgusted face image with the top half of one sad, afraid, or angry face image. Following Calder et al., images from only four of the actors are used.

Composite Gabor patterns are the result of convolving these composite images with Gabor filters and z-scoring. As the model must identify the expression in one half of the example, one half of the composite Gabor pattern is attenuated by a fraction of 0.125. Noncomposite Gabor patterns are created from the composite Gabor patterns. The half of the pattern that is attenuated is misaligned with the other half by replacing the components of the attenuated half corresponding to the right side of the face with the components corresponding to the left side and zeroing the components corresponding to the left side. These are projected onto the principal components of the same training set as the first experiment. The network is trained as in the previous experiment, and tested on identifying the expression in one half of both composite and noncomposite examples.

Results: The results are shown in Figure 3. These results indicate that our classification performs better on noncomposite test examples than composite test examples. As the top and bottom face halves are aligned in the composite examples, there is incorrect configural information in these examples that is not present in the noncomposite examples. Therefore, this result indicates that incorrect configural information disrupts our model's expression recognition. The trend in classification error for these two types of test examples is similar to the trend reported for human response time for these two types of examples, as shown in Figure 3.

Figure 3: Experiment 2 results. (a) Average error proportion for composite, noncomposite, and half face test examples. Vertical bars indicate standard deviations. (b) Human response times for expression classification of composite and noncomposite test examples

Experiment 3

In Calder et al.'s Experiment 4, they investigated the interference between identity and expression processing. They noticed that when two happy expressions were combined from different individuals, the new image looked like a happy person who was a new individual, different from the two source individuals (see Figure 2(b)). They hypothesized from this that "the configural information used to encode facial identity may be different from that used to code facial expression." They suggested that if the two kinds of processing could be selectively disrupted, then that would be support for this two-representation model. Note that our model has one representation, corresponding to the principal components layer. If we can obtain the same results, then we will show that their conclusion, that there are two representations, is unwarranted.

This experiment involved three types of composite stimuli. Same identity with different expression (SID/DE) composite examples require that the identity of the actor in both halves be the same but the expression in each half be different. Different identity with same expression (DID/SE) composite examples require that the identity of the actor in each half be different but the expression in each half be the same. Different identity with different expression (DID/DE) composite examples require that the identity of the actor in each half be different but the expression in each half be the same. Figure 2(b-d)

shows examples of all three types.

The model is trained on all the whole and half face examples for ten actors. Following Calder et al., the model must classify the expression and identity in the bottom half of the composite test examples constructed from three of the actors. In order to test for identity performance, Calder et al. trained their subjects on both identity and expression for the three actors they used to create the composite test stimuli. Hence these stimuli were included in the training set. Three additional localist outputs were included to learn the identity of these three actors. The seven remaining actors were trained to produce all 0's on these units. Following Calder et al., for the three test subjects, the composite examples constructed from them for testing purposes only use the happy, surprised, and disgusted expressions. We stopped training by using a holdout set composed of the remaining four actors from POFA that were not used in any of the Calder et al. experiments. The network was trained until error on the holdout set was minimal, and tested on all three types of composite examples.

Results: The results are shown in Figure 4. While both expression and identity were classified without error on all types of composites, there was a significant difference in a standard measure of reaction time from feed-forward networks: 1 - the maximum output. Figure 4(a) shows the reaction time of our network on the relevant stimuli.

Figure 4: Experiment 3 results. Panel (a) shows the effect of composite type on our network reaction time for identity and expression recognition. Panel (b) is derived from (Calder et al., 2008).

When classifying expression (dashed line), the model responds more quickly when the expression is the same in both halves of the composite example. Crucially, the model is not slowed more in the DID/DE case than the SID/DE case. The same result is true for identity classification. When classifying identity, the model is faster when the identity is the same in both halves of the composite example. Crucially, the model is not slowed more in the DID/DE case than the DID/SE case. In fact, it is slightly faster. The pattern of these results are equivalent to the pattern of the response times in the human experiments (Figure 4(b)).

Analysis

In this section we examine the kind of representation that the network is using for this task. In particular, we examine the principal components of the Gabor filters. Calder et al. showed that the principal components of gray scale images taken from the POFA database show a separation in terms of identity and expression. That is, there are components that best separate expressions, and different components that best separate the identities of the models in the POFA.

The principal components that best discriminate a data set, assuming the data samples are normally distributed, are those that minimize the variance of the samples within each class, while maximizing the total variance of all the samples. Therefore, we can rank the approximate discriminating power of each principal component by the Wilk's Λ value: the within-class scatter divided by the total scatter of the samples. The smaller the Wilk's Λ , the greater the discriminating power.

The two Wilk's Λ values for each principal component were computed for the two face recognition tasks compared in this paper: expression recognition and identity recognition. Only two components out of the highest 10 ranked principal components for each task overlapped. The 5th and the 19th principal components were ranked in the top 10 for both

expression and identity recognition, but other than that the top ten components for the two tasks were disjoint.

This suggests that the principal components used to encode expression are separate from those used to encode identity. Figure 5(a) and (b) show the projections of the identity classes and expression classes on the most discriminating expression principal components. It is apparent that these components separate expression better than identity. Figure 5(c) shows the identity Wilk's Λ value plotted against the expression Wilk's Λ value, for corresponding principal components.

Discussion

Our results suggest that our simple neural network model can explain a variety of effects in psychological research in expression recognition. We found that our model showed nearly the same pattern of results in discriminability of expressions from half faces. In order to obtain this result, we had to change our model in two ways. First, we modeled the attentional process as an inhibition of irrelevant information, an approach that is well supported in the literature. Second, we had to add training on half faces to our model. We suggest that this modification is independently motivated by the fact that people foveate on different parts of the face when performing such tasks. Future research should concentrate on actually implementing an eye movement mechanism that is modulated by the task. Our previous model of scan paths (Yamada and Cottrell, 1995) only used bottom up information. Top down, task-related information can be incorporated by using the mutual information between the features and the categories – essentially, feature selection.

Second, we showed that our model's error patterns when shown composite versus non-composite faces follow the reaction time pattern in the human subjects data. That is, where our model makes more errors, the humans have longer reaction times. In an unreported experiment, we found the correct pattern

Figure 5: PC Analysis: (a) Plots of each class of expression on the two most discriminating expression principal components; (b) Plots of each class of identity on the two most discriminating expression principal components; (c) Identity and expression Wilk's Λ values for corresponding principal components.

of reaction times when the network is only shown a half face versus a composite face. This suggests that either the human subjects do not look at the other half of the face at all when they are misaligned, or that a greater degree of attenuation of the misaligned half should lead to results more in keeping with the RT data.

Third, our model showed that it is not necessary to posit two independent representations for identity and expression processing. Since the representation at the principal components layer is a set of orthogonal vectors, and the categorizer is a single layer perceptron, this suggests that each output unit is simply cutting off a different corner of the feature hypercube, and the learned hyperplane is simply orthogonal to the non-informative directions of variation. This is exactly what one would expect given this type of model, and so there is no mystery in our results.

This result might also have been expected given previous results examining the principal components of gray scale images of facial expressions directly (Calder et al., 2001), where it was found that expression and identity tended to load on different principal components. The main difference here is that our principal components are performed on a more biologically plausible representation of faces than gray scale images. However, we find that when we do a similar analysis to that carried out by Calder et al. (2001), we also find that the representation loads expression and identity on orthogonal components. Does this mean that we have two representations? If one thinks of each principal component as a linear "neuron," and the projection of an input on that component as its activation, then observing these activities will appear to show units that respond to identity, and other units that respond to expression. One could argue that these are then separate representations.

However, we argue that when viewed ontologically these representations were developed to be orthogonal *with respect to one another*. That is, due to the

constraint that the principal components must be orthogonal, the representation of emotion is made in the context of and in competition with the representation of identity, as these are the major directions in which the data vary. On the other hand, one can say that this is a *functional* separation of the representations, and indeed, it is.

Cognitive Precursors to Science Comprehension

Kimberly G. Cottrell (kcottrel@odu.edu)

Department of Psychology, Old Dominion University
Norfolk, VA 23529 USA

Abstract

This study examined the ability of cognitive factors (i.e., prior domain knowledge, reading ability, and metacognitive reading strategies) to predict students' comprehension of science texts and students' performance in an introductory psychology course. Both prior knowledge and reading ability reliably predicted comprehension of the science text (about sensory memory). Prior knowledge was the best predictor for exam performance. However, greater knowledge provided no benefit for students who did not use certain types of metacognitive reading strategies. Also, the tendency to use previewing strategies only benefited students if they possessed sufficient prior knowledge.

Introduction

What cognitive abilities are most important to a student entering a college level science course? If we assume that science course performance relies on factors related to science comprehension, then cognitive factors such as the students' level of reading ability, their prior knowledge of the domain area, and students' knowledge and use of metacognitive reading strategies should play key roles in students' course performance. Hence, the purpose of this research was to establish whether these cognitive factors were predictive of students' comprehension of science texts as well as their performance in a science course (in this case, introductory psychology).

There is no doubt that better readers better comprehend text (Perfetti, 1985) – because, of course, that is the underlying definition of reading skill. Skilled readers also tend to experience the reading process as more automatic and effortless than less skilled readers (Underwood, 1997). Skilled readers tend to make reading process decisions below the level of consciousness, particularly when reading familiar material. Thus, skilled readers unconsciously, or with very little conscious effort, understand the thoughts communicated through the texts and are reminded of the knowledge they have regarding the topic covered within a text (Underwood, 1997). Furthermore, skilled readers approach confusing sentences or passages by incorporating their prior domain knowledge to help them better understand the text (Collins, 1994). Thus, it would be expected that not only reading skill, but also prior knowledge would provide considerable benefits to science text comprehension and by consequence to students' course performance.

Researchers have established that prior domain knowledge has a strong effect on text comprehension and memory. Bransford and Johnson (1972) first established that prior knowledge improves readers' memory for written information. They showed that when readers were provided with a prior schema via a passage title or a picture, readers recalled twice as much from the passage compared to those who were not provided with prior schematic information. Essentially, the passage title activated the appropriate prior knowledge, or schema, that allows the reader to understand and thus remember the passage. Chiesi, Spilich, and Voss, (1979) demonstrated that readers with greater prior knowledge of baseball better understood and remembered a passage concerning baseball, regardless of the participants' age or reading ability. Further research has demonstrated that prior knowledge has a pronounced effect on comprehension of difficult expository texts, such as those found in science textbooks. Readers with greater prior knowledge exhibit superior comprehension and thus enhanced learning compared to those with less prior knowledge (Alexander, Kulikowich, & Schulze, 1994; Chiesi et al., 1979; McNamara, 2001; McNamara & Kintsch, 1996; McNamara, Kintsch, Songer, & Kintsch, 1996). Therefore, we can expect that prior knowledge will have a substantial effect on science course performance, perhaps more so than reading skill.

Whereas prior knowledge is certainly critical for successful text comprehension and course performance, students' metacognitive knowledge, such as their knowledge of metacognitive reading strategies, may also play an important role. Generally, metacognition refers to an individual's ability to think about thinking. More specifically, metacognition can be defined as an individuals' ability to self-monitor, self-assess, and self-evaluate. These processes help a learner determine why a process such as reading a science textbook is difficult, and then potentially overcome the difficulty.

Metacognition when applied to reading refers to the process of monitoring comprehension and the use of strategies to improve comprehension (Forget & Morgan, 1997). Reading strategies such as summarization, mental imagery, mnemonic imagery, question generation, answering self-generated questions, and look-backs have all been shown to enhance text comprehension (Pressley & Woloshyn, 1995). Chi and Bassok (1989) found that successful students tended to employ reading strategies such as generating elaborations and paraphrases, monitoring and creating statements, and producing self-explanations. In turn, these strategies enhanced their understanding of the

text material (see also, Chi, DeLeeuw, Chiu, & LaVandcher, 1994). Chi and Bassok also found that the students were more likely to generate explanations of the material covered within a text when they monitored and detected the points that they did not successfully understand. In addition, more successful students' self-explanations tended to include additional knowledge compared to less successful students who were more likely to simply paraphrase the text material.

Chi, Bassok, Lewis, Reimann, and Glaser (1989) found that successful students showed a tendency to use strategies such as explaining and justifying example-exercises in a science textbook to themselves whereas less successful students were not as likely to show this tendency. When the less successful students explained the exercise to themselves, they did not seem to connect their prior knowledge with the information covered within the science textbook. The study also found a tendency for the successful students to accurately monitor and detect when they understood a concept as well as when they did not fully comprehend or understand a concept. The less successful students did not show this tendency when attempting to detect comprehension failures of concepts covered within a science text.

Reading strategy instruction also improves reading comprehension. Bereiter and Bird (1985) found that when readers were taught strategies such as restatement, backtracking and problem solving, there was a significant increase in reading comprehension. McNamara and Scott (1999) found that when students in a college level science course were trained to use reading strategies to improve self-explanation, they had superior course grades compared to their counterparts who did not receive this training. Moreover, this training was more beneficial to students with less prior knowledge than for those who had greater prior knowledge. In essence, the training helped the students to overcome their knowledge deficits.

Collins (1994) also notes that metacognition affects an individual's ability to integrate prior knowledge with incoming novel information from a textbook, such as those textbooks used in science courses. As indicated earlier, prior knowledge assists an individual's ability to comprehend incoming information. Thus, an individual's metacognitive skills may assist him or her in incorporating their prior knowledge with the new information from the textbook.

In summary, the literature indicates that reading skill, prior knowledge, and the knowledge and use of metacognitive reading strategies are important tools in science comprehension. Thus, the current study examines whether reading ability, prior domain knowledge, and metacognitive reading strategies are related to course performance in an introductory psychology course at Old Dominion University. These factors were assessed at the beginning of a semester to determine their ability to predict students' comprehension of a science text and students' course performance. Our secondary goal was to reveal whether specific metacognitive reading strategies were more or less associated with reading ability, science text comprehension, and prior knowledge.

Reading ability was expected to facilitate readers' comprehension of text material and thus improve course performance. Additionally, it was expected that prior knowledge would have a profound effect on science course performance as well as comprehension of a science text. Those students who have prior knowledge of the domain of a text should perform better on comprehension measures of that material because they have the opportunity to incorporate that prior knowledge with the text material. However, knowledge and use of metacognitive reading strategies should enhance that ability by the reader strategically incorporating his or her prior knowledge with the novel material from the text. However, for those students who lack the adequate knowledge needed to comprehend difficult texts, such as science textbooks, the use of metacognitive reading skills may compensate for the lack of prior knowledge (see e.g., O'Reilly and McNamara, 2002). Metacognitive reading strategies may assist the learner to monitor their comprehension of the text material and thus actively attempt to understand the material.

Method

Participants

The sample consisted of 144 undergraduates enrolled in Introduction to Psychology at Old Dominion University. The participants included 57 males and 87 females with a mean age of 19 years. The majority of the participants were freshman ($n=111$). The remaining sample consisted of 21 sophomores, 8 juniors, and 4 seniors. They were given extra credits points in the psychology course of their choice for their participation.

Procedure

The experiment involved two sessions, which took place during the regularly scheduled class periods. In the first session, participants were invited to participate and given the Metacognitive Strategies Index (MSI) to complete at home. (There was no instruction of metacognitive reading strategies.) In the second session, participants were administered the prior knowledge test (19 min), the Nelson Denny reading test (15 min), and the sensory memory test with the comprehension questions (8 min). Students' grades were provided by the instructor at the end of the semester.

Materials

Metacognitive Reading Strategies Knowledge and use of metacognitive reading strategies was assessed using the Metacognitive Strategies Index (MSI; Forget, 1999). This was a 25-item multiple-choice questionnaire. Studies conducted by Forget in content areas at the high-school level found validity and test-retest reliability to be high (Forget, 1991; Forget & Morgan, 1997; Forget, 1999). The questions determine what the student does before, during, and after reading a text. For the purpose of this study, four sub-factors were examined (1) predicting and verifying (predicting the content and evaluating predictions and creating new ones), (2) previewing the text, purpose setting, and self-questioning, (3) drawing from background knowledge (activating and incorporating information from

background knowledge), and (4) summarizing the content. The reliability of the MSI computed by Cronbach's Alpha was .66. Reliability of sub-factor (1) predicting and verifying was .30, of sub-factor (2) previewing, purpose setting, and self-questioning was .38, of sub-factor (3) drawing from background knowledge was .46, and for sub-factor (4) summarizing and applying fix-up strategies was .29.

Demographics Demographics, motivation, effort, and education were assessed using a questionnaire consisting of 15 questions. The questions assess how much time and effort the students devote to the course as compared to how much time and effort they devote to other courses (i.e., "How many hours per week do you plan to devote to reading and studying for this course?"). The questions also determine how many science courses the participants have completed and how much they enjoy reading and learning scientific material as well as non-scientific material. Examples are: "How much do you enjoy reading?" and "How much do you enjoy learning information about science?"

Prior Knowledge Prior knowledge was assessed using an unpublished prerequisite knowledge test developed in collaboration with Linda Buyer at Governors State University in Illinois. The 48 multiple-choice questions were developed based on the concepts covered within three textbooks used for introductory psychology courses that were assumed known to the reader by the textbook authors. The questions included psychology specific questions (i.e., "Which person is most closely associated with the concept of the unconscious?"), general knowledge questions (i.e., "Which of the following is a logarithmic scale?"), and research methodology questions (i.e., "How is sample size related to the accuracy of population estimates derived from sample data?"). The questions were presented in random order. Reliability of the prior knowledge test computed by Cronbach's Alpha was .67.

Reading Ability Reading ability was evaluated using form G of the Nelson Denny adult reading comprehension test (Brown, Fishco, & Hanna, 1993). The measure consists of seven passages and 38 questions. The participants were instructed to read a passage and then answer the comprehension questions regarding that particular passage. They were permitted to look back on the passages to answer the comprehension questions. Reliability computed by Cronbach's Alpha was $\alpha=.88$.

Science Comprehension The text consisted of a 307-word passage on the topic of sensory memory adapted from Lefton (pp. 195-196; 2000). The reading ease was 31.3 and the Flesch-Kincaid Grade level was 12. Twelve open-ended comprehension questions were used to measure comprehension of the passage. Six of the 12 questions were bridging questions, which require the reader to make inferences from two or more sentences in the text (i.e., "What was the dependent variable in Sperling's experiment?

That is what did he measure?") and the remaining 6 were text-based questions which require the reader to use only one sentence in order to successfully answer the question (i.e., "What is sensory memory?"). The students were allotted 8 minutes to read the passage and answer the questions, but were allowed to refer back to the passage to answer the questions. Therefore, performance on the questions assesses comprehension, but does not necessarily assess memory or learning. The participants were allotted 8 minutes to complete the exercise. Reliability of the science text comprehension questions computed by Cronbach's Alpha was .33.

Results

The alpha level was set at .05; hence, probability values are only reported for marginal results. As might be expected, knowledge and reading skill were highly correlated ($R=.63$), but were not reliably correlated with performance on the MSI. Text comprehension performance was measured in terms of proportion correct on the open-ended questions. Two raters scored the comprehension questions and discrepancies (12% of the scores) were resolved via discussion, yielding a final set of scores.

Demographics

A standard multiple regression was computed to determine whether variables such as the students' amount of effort in the class, motivation, enjoyment for learning science and non-science material as well as the number of previous science courses taken by the student were associated with comprehension of the sensory memory text as well as course performance. For comprehension of the sensory memory passage, the overall regression model was significant, $F(15,121)=2.29$ accounting for 12% of the variance. Total points on the SAT in high school was the only significant predictor, $\beta=.35$, $sr^2=.09$. For average exam performance, the overall regression model was reliable, $F(15,121)=1.93$ accounting for 9% of the variance. The only reliable predictor was high school grade point average, $\beta=.33$, $sr^2=.08$. Hence, neither course effort nor reading enjoyment were significant predictors of performance in this study.

Predicting Comprehension and Exam Performance

Our first question regarded the ability of prior knowledge, reading ability, and the MSI to predict science text comprehension and course performance. Regression analyses were performed for each dependent measure including prior knowledge, reading ability, and metacognitive reading strategies as predictor variables.

Science Text Comprehension For science text comprehension, the overall regression model was reliable, $F(3,140)=30.70$, accounting for 38% of the variance. Performance on the MSI did not predict performance, whereas both prior knowledge, $F(1,140)=9.54$; $\beta=.27$, $sr^2=.04$, and reading ability, $F(1,140)=23.68$; $\beta=.41$, $sr^2=.10$, reliably predicted comprehension. High-knowledge

students scored significantly higher on the comprehension questions ($M=49\%$ correct) than low-knowledge students ($M=33\%$ correct); and similarly, skilled readers showed better comprehension ($M=50\%$ correct) than less-skilled readers ($M=31\%$ correct). Separate analyses did not reveal any interdependencies between prior knowledge and reading ability.

Average Exam Performance Average Exam performance in this course was based on the top five of six exams. Analyses included students who completed at least four of the six exams ($n=136$). In terms of average exam performance, the overall regression model was reliable, $F(3,132)=13.46$, accounting for 25% of the variance. Neither reading ability, $F(1,132)=2.38$, nor performance on the MSI, $F(1,132)=3.24$, reliably predicted exam performance. Prior knowledge, in contrast, accounted for 21% of the variance, $F(1,132)=30.85$; $\beta=.48$, $sr^2=.14$. Students with greater prior knowledge about concepts related to psychology when beginning the course scored significantly higher on the exams ($M=0.80$) than did low-knowledge students ($M=0.72$). In addition, the effect of knowledge on exam performance remained stable across exams, thus, prior knowledge affected performance equivalently across all of the exams.

Metacognitive Reading Strategies

Our second question regarded whether the sub-factors of the MSI differentially predicted reading skill, science text comprehension, and course performance. The sub-factors included (1) predicting and verifying, (2) previewing, purpose setting, and self-questioning, (3) drawing from background knowledge, and (4) summarizing and applying fix-up strategies.

Reading Ability None of the four metacognitive sub-factors reliably predicted scores on the Nelson Denny reading test.

Science Comprehension Performance on the science text comprehension questions was reliably predicted by sub-factor 3 (drawing from background knowledge), $F(1,140)=4.37$; $\beta=.21$, $sr^2=.03$. The students who were more likely to use prior knowledge while reading scored significantly higher on the comprehension of the science text ($M=42\%$), than those students who were less likely to use knowledge ($M=37\%$). This relationship remained significant when prior knowledge and reading ability were included in the regression equation. Although, one might expect that drawing on background knowledge would depend on the student's prior knowledge, this interaction was not reliable.

Figure 1. Exam Performance as a Function of Prior Knowledge, Summarization Reading Strategies, and Previewing Reading Strategies

Exam Performance Performance on exams was reliably predicted by sub-factor 2 (previewing, purpose setting, and self-questioning), $F(1,131)=4.16$; $\beta=.19$, $sr^2=.03$ (High $M=0.77$; Low $M=0.73$) and by sub-factor 4 (summarizing and applying fix-up strategies), $F(1,131)=4.33$; $\beta=.19$, $sr^2=.03$ (High $M=0.77$; Low $M=0.73$). However, these effects were not reliable when prior knowledge was also included in the regression model indicating that prior knowledge is more predictive of exam performance. Moreover, further analyses revealed that these factors were interdependent. An interaction between knowledge and previewing indicated that students who were more likely to use previewing strategies (i.e., sub-factor 2) only benefited from these strategies on the exams if they possessed sufficient knowledge, $F(1,128)=7.95$. In addition, there was a three-way interaction between knowledge, previewing, and summarization, $F(1,128)=4.65$ (see Figure 1). Students who were less likely to use previewing strategies but more likely to use summarization strategies showed a marginal effect of prior knowledge, $F(1,36)=3.31$, $p=.08$. Students who were more likely to use previewing strategies, regardless of the extent of their use of summarizing strategies significantly benefited from their prior knowledge on exams (High Summary $F(1,46)=14.33$; Low Summary $F(1,19)=21.36$). Finally, greater knowledge provided no benefit for students who did not use either type of reading strategies, $F<2$. Looking at the interaction from a different angle, the effects of strategy use were not reliable for low-knowledge students. In contrast for high-knowledge students, there was a reliable effect of previewing, $F(1,47)=7.84$, and marginal interaction of previewing and summarizing, $F(1,47)=3.61$, $p=.06$.

Discussion

The purpose of this study was to determine which cognitive abilities were precursors to science comprehension, and by consequence to students' performance in a science course (in this case, introductory psychology). Hence, we examined students' prior knowledge, reading ability, and metacognitive reading strategies at the beginning of a semester and related performance on these measures to students' ability to comprehend a science text (about sensory memory) and students' average exam scores. In addition, we determined whether specific metacognitive reading strategies differentially predicted reading ability, science text comprehension, and course performance.

As hypothesized, prior knowledge strongly predicted students' comprehension of the sensory memory passage as well as their exam performance. High-knowledge students showed a 16 percent advantage on comprehension questions in comparison to low-knowledge students. Similarly, students with greater prior knowledge about basic psychological concepts performed about 8 percent better on the course exams than low-knowledge students. Indeed, prior knowledge was the only reliable predictor of exam performance, accounting for 21 percent of the variance. Moreover, there was not a decline in the effect of prior knowledge throughout the semester. Hence, students did not overcome their knowledge deficits as the course proceeded.

Reading ability was a strong predictor of text comprehension, even more so than prior knowledge. The fact that reading ability did not predict exam performance could imply that the exams did not include information covered solely within textbooks rather was primarily based on information covered within the lectures; thus reading comprehension would not be necessary to succeed in the course. In addition, this would mean that our reading ability measure would be a poor predictor of lecture comprehension. Alternatively, the type of reading ability measure could be at fault. That is, perhaps the Nelson Denny reading test does not tap into the same processes involved in comprehending a course textbook. To contradict that argument, however, it was found that reading ability was the strongest predictor of comprehension of the science text, which was derived from an introductory psychology textbook.

In addition, it was found that neither the overall score nor the four metacognitive sub-factors predicted reading ability. This result indicates that the Nelson Denny reading test does not rely heavily on strategy use. This result may be expected because the Nelson Denny reading test primarily covers relatively familiar material, whereas metacognitive reading strategies may be most helpful for less familiar or difficult material.

Students' overall score on the Metacognitive Strategies Index (MSI) did not reliably predict either exam scores or science text comprehension. However, when the sub-factors were considered, it was found that *drawing from background knowledge* was predictive of science text comprehension. The influence of this type of reading strategy was positive regardless of students' prior knowledge and reading ability. This result further supports

the importance of teaching both high- and low-knowledge students to integrate prior knowledge with new information when reading difficult texts such as science textbooks (e.g., McNamara & Scott, 1999).

The two sub-factors, *previewing*, *purpose setting and self-questioning* as well as *summarizing and applying fix-up strategies* predicted exam performance; however, this was dependent on the amount of knowledge the students' possessed. The students' use of previewing strategies was only beneficial on the exams when they possessed sufficient prior knowledge. The purpose of previewing is to activate knowledge schemas. These schemas presumably help the student to prepare for the learning process – just as a story title helps the reader understand a passage (Bransford & Johnson, 1972). However, without the necessary knowledge about the topic, previewing is of little utility.

In addition, it was found that students with low-knowledge did not benefit reliably from strategy use on exams (cf., O'Reilly & McNamara, 2002). Thus, in contrast to the results for text comprehension, it was found for exams that strategy use did not help to compensate for knowledge deficits. High-knowledge participants benefited from strategies, and most importantly, having more prior knowledge did not benefit students who did not use either of the metacognitive reading strategies. Hence, knowledge and strategy use are critically intertwined.

There are several limitations to this study. First, this study was correlational, and thus causal relationships cannot be assumed. Clearly, additional experimental studies are necessary to more completely understand these issues (cf., McNamara & Scott, 1999). Second, the sample was college students all enrolled in the same introductory psychology course and most of the students were freshmen in their second semester of college. Thus, the results of this study may not generalize to other populations. Additionally, this study may not adequately tap into science comprehension per se since the students are enrolled in a psychology course and the sensory memory text was derived from an introductory psychology textbook. The predictors of comprehension of passages within a psychology textbook may differ from those predictors of comprehension of a biology textbook or textbooks used in other hard sciences. Future research in this area could be to examine what factors predict comprehension of texts and course performance in other science courses such as biology or chemistry (e.g., see O'Reilly & McNamara, 2002). Finally, it may be beneficial to examine predictive factors of science comprehension for college students compared to younger students such as those in high school.

In conclusion, these results underline the notion that students should be taught to utilize strategies when reading texts, particularly those found in science courses. It is important, though, to understand which strategies may be more or less helpful under different circumstances. This study is a small step toward better understanding what these circumstances may be.

Acknowledgments

We would like to thank Linda Buyer who developed the prior knowledge test for this study. We would also like to thank the ODU Strategy Lab for helping us administer the tests to the students, and Erin McSherry for helping to score the comprehension questions. This project was partially supported by an NSF IERI grant (REC-0089271) to the second author. Abstract

We argue that problem solvers can, in certain cases, solve target problems by transforming perceptual simulations of solutions to analogous source problems. We further argue that source diagrams may facilitate the process, but only if they convey physical affordances consistent with the necessary transformations. We conducted an exploratory study in which participants were asked to solve a source and a target problem. We identified two properties of extemporaneously drawn source diagrams – view and configuration – that were highly correlated with the production of analogous solutions to the target problem. We speculated that view and configuration influenced the ease with which certain simulated transformations were performed. The results of two additional experiments in which the view and configuration of source diagrams were independently controlled further support the claim.

Introduction

In this paper we explore the functioning of diagrams in analogical problem solving. Specifically, we investigate how contextual aspects of diagrams – things ranging from depicted physical details to intrinsic properties like perspective, orientation and scale – might afford the kind of simulated physical transformations needed to convert a solution to one problem into a solution to another. In the next two sections we briefly outline our claims concerning diagrams, simulations and affordances, and how they might relate to analogy. In the remaining sections we present the findings of three experiments designed to both illustrate and test those claims.

Diagrams, Simulations and Affordances

One way external diagrams can function in problem solving is by scaffolding perceptual, or analog, simulations in the perceptual and motor cortices of the brain (Barsalou, 1999; Glenberg, 1997). Perceptual simulations have been found to facilitate spatial reasoning (e.g., Kosslyn, 1994) as well as various forms of conceptual reasoning (e.g., Barsalou, Solomon & Wu, 1999; Glenberg & Robertson, 2000; Stanfield &

Zwaan, 2001; Fincher-Keifer, 2001). They could potentially benefit problem solving by facilitating the testing and general exploration of candidate solutions.

We argue that the way a diagram is drawn affects not only what is perceptually simulated but also how the resulting simulation can be perceptually transformed. A long history of findings, dating back to Cooper and Shepard's (1973) chronometric studies of mental rotation, support the basic premise that simulations are transformed through simulated motor activity. More recently, researchers have found that simulated transformations are motorically structured and constrained. The ease with which imagined body parts are mentally rotated, for example, parallels the ease with which those parts can be rotated in actuality (Parsons, 1987). In addition, concurrent motor activity consistent with simulated transformations of imagined objects tends to make those transformations faster and more accurate, while inconsistent activities produce interference (Wexler, Kosslyn & Berthoz, 1998). Generally speaking, simulated transformations appear to be constrained in the same way real interaction with the physical world is constrained. Insofar as contextual aspects of diagrams would help determine the physical properties of simulated objects (e.g., texture, shape, mass, etc.) and the context in which they are perceived (e.g., perspective, orientation, scale, etc.), those aspects act as transformational affordances by facilitating certain simulated transformations and inhibiting others.

A finding that illustrates the idea that diagrams convey transformational affordances comes from a study by Schwartz and Black (1996) in which people were shown a diagram of two gears meshed together, one larger than the other, and asked whether two marks, one on the circumference of each gear, would eventually line up if the gears were rotated. By comparing response times against the initial angular disparity of the marks, Schwartz and Black were able to identify different strategies used to complete the task, one of which appeared to be perceptually simulating the two gears rotating together. Ultimately, Schwartz and Black were able to constrain the strategy people used

by manipulating the gear diagrams. In particular they found that the simulated-rotation strategy was most likely to be used when the contacting surfaces of the gears were depicted as rough rather than smooth, as if roughness made it easier to imagine one gear driving the other. In this case a physical property depicted in the diagram appears to have affected the ease with which associated perceptual simulations were subsequently transformed.

Analogical Problem Solving

In analogical problem solving, problem solvers start with a solved "source" problem that is similar in some way to an unsolved "target" problem. If a problem solver is aware that the two are related, he or she will need to map the source problem onto the target, thus identifying which problem elements and constraints are identical, which are comparable, and which are irrelevant. Ideally, a mapping will be formed that allows the problem solver to transfer additional aspects of the source to the target, producing a target solution. Although most accounts of analogy are based on perceptually neutral representations (e.g., Gentner, 1983; Gick and Holyoak, 1983), we argue that people can, in certain situations, perceptually simulate source solutions and transform the simulations into solutions to target problems. Following the hypothesis presented in the previous section, we further argue that affordances associated with source diagrams might influence the likelihood that an analogical solution is produced by constraining what transformations can be executed.

Experiment 1

To explore how diagrams influence analogical problem solving we devised an open-ended experiment in which participants were given two superficially dissimilar but analogous problems and asked to 1) consider possible links between them, 2) list whatever similarities they found, and 3) try to solve them. The first problem was written to be easier than the second, the hope being that participants would solve it and thus have a source they could apply to the second problem. No independent variables were controlled. Instead, variations in solutions to the easier problem – in particular variations in the contextual aspects of spontaneously produced sketches – were analyzed after the fact. Correlations between various contextual properties and the production of analogous solutions to the harder problem were then sought.

The easier of the two problems – the one written to be a potential source for the harder problem – involved designing a door system for a laboratory that would give workers free access to the lab space while keeping the air outside the lab from contaminating the air inside. It was assumed that most participants would come up with a redundant-door solution, one that involved either two sets of doors on either side of a vestibule or a revolving door. The harder problem – the one written to

be the target – involved designing a pole that suspended a device several feet off the side of a truck. The pole was described as sticking out in such a way that it ran into signposts on the side the of the road (Figure 1). The problem was to design the pole so that it could pass through signposts at a right angle. Ideally, if participants came up with a redundant-door solution to the door problem they would use it to come up with a redundant-pole solution to the pole problem. They might, for example, specify two poles, one that moved out of the way while the other stayed in place and vice versa.

To form an analogy between the door problem and the pole problem requires overcoming not only superficial differences (e.g., differences in objects and object attributes) but also a key structural difference in their respective perceptual contexts. In the door problem, passing through the door is natural; the problem is that it lets bad air in and good air out. In the pole problem, by contrast, passing one object through the other is not natural, and the problem is to make it so. Furthermore, the pole problem involves modifying the thing in motion, while the door problem involves modifying the thing being passed through. Thus, to map a simulated redundant-door solution onto the pole problem ultimately requires a shift in one's physical frame of reference. One must either 1) imagine that the sign post in the pole problem is the lab worker in the door problem, or 2) imagine that the lab boundary in the door problem is the pole in the pole problem. The latter means imagining an otherwise rooted lab boundary in motion, while the former means imagining an otherwise rooted sign post in motion.

Figure 1 The pole problem: Participants are asked to design a pole that can pass through a signpost.

Transforming the motional context of a simulated redundant-door solution may not be easy. Such a shift might depend on what sort of transformational affordances are present, which might, in turn, depend on the contextual properties of an external diagram. We argue that a diagram of a redundant-door solution might, by scaffolding a perceptual simulation, facilitate the use of such a solution in solving the pole problem, but only if the contextual properties of the diagram afford the shift in motional context required to align the two problems.

Materials and Procedure

The experiment was administered in booklet form. The door problem was printed at the top of the first page

and the pole problem just below it. Instructions on the first page asked participants to write down as many similarities between the two problems as they could in 4 minutes. The second page of the booklet was divided vertically, the top containing instructions asking participants to write down a solution to the door problem, the bottom containing instructions asking participants to write down a solution to the pole problem. The instructions specified that they would have 5 minutes total. As participants were led through the booklet they were reminded to carefully read the instructions before starting each task. When they turned to the second page they were verbally told they could draw pictures if it helped them articulate their solutions.

Participants

Two hundred and nine participants were recruited from an introductory psychology class at Georgia Tech to participate in exchange for class credit. The experiment was administered in one large group during a regularly scheduled class session.

Results and Discussion

We first analyzed similarities participants reported prior to solving the problems. Most participants reported superficial similarities, such as that both problems involved engineers. A few also reported highly abstract similarities, such as that both problems involved an obstacle that prevented a device from working. More interestingly, some participants reported that both problems involved something passing through a solid barrier. Although the requirement that something pass through a barrier is clearly stated in the pole problem, it is not stated at all in the door problem. The objective in the door problem is, in fact, opposite that of the pole problem: Something with a penetrable (as opposed to solid) boundary needs to be redesigned to prevent something from getting through (as opposed to allow something through). Despite the implicit nature of the pass-through similarity, 60 of the 209 participants (29%) reported it.

We next analyzed solutions produced for the two problems. Solutions to the door problem were classified as either redundant-door solutions or non-redundant-door solutions, the former being those that included one or more of the following: 1) a verbal reference to two doorways, 2) a verbal reference to an airlock, 3) a verbal reference to a revolving door, 4) a diagram showing two doorways, 5) a diagram showing an airlock, or 6) a diagram showing a revolving door. As expected most participants (184, or 88%) produced some kind of redundant-door solution.

Fewer students, by contrast, were successful in solving the pole problem. Solutions to the pole problem were first classified as either analogous to the door problem or non-analogous. Analogous solutions were those that made use of redundancy. Specifically, a solution was deemed analogous if one part remained in place while another part moved out of the way and vice

versa. Such solutions included those with multiple latches (with one latch opening at a time), multiple poles (with one pole retracting at a time), or rotating devices (with one end swinging out of the way as the other end swung into place). Of the 209 participants, 33 (16%) produced analogous solutions to the pole problem. An example of an analogous solution is shown alongside a non-analogous solution in Figure 2

Not surprisingly, participants were more likely to generate an analogous solution to the pole problem if they generated a redundant-door solution to the door problem. Of the 184 participants who generated redundant-door solutions, 31 (17%) produced analogous solutions to the pole problem, while only 2 of the other 25 participants (8%) produced them. Analogous solutions to the pole problem were also correlated with the reporting of pass-through similarities. Of the 60 participants who reported pass-through similarities, 17 (28%) produced analogous solutions to the pole problem, compared to 16 of the 149 (11%) who did not.

Figure 2 A solution to the pole problem that is analogous to a redundant-door solution to the door problem (left) and one that is not (right).

The remaining analyses concern the diagrams participants drew to illustrate their solutions to the door problem. Of the 184 participants who produced redundant-door solutions, 131 drew at least one diagram. Diagrams alone were not correlated with analogous solutions to the pole problem. Of the 131 who drew diagrams, 22 (17%) produced analogous solutions to the pole problem, while 9 of the remaining 53 participants (17%) also produced them. This is not inconsistent with the argument made earlier about the role of diagrams in problem solving. Of interest is not whether diagrams in general help but whether certain types of diagrams are more highly correlated with the production of analogous solution than others.

To roughly classify diagrams according to transformational affordances we looked at two diagram properties: view and configuration. View was coded as either plan (viewed from above), elevation (viewed from the side), perspective, or ambiguous (either plan or elevation). Configuration was more varied. After reviewing all redundant-door diagrams, 17 distinct configuration types were identified based on the spaces that were depicted and their organization. From these 17 types, two higher-level categories were defined: 1) single-space diagrams, or those in which the only space

depicted was the space between the redundant doors and 2) multiple-space diagrams, or those in which additional spaces were depicted. A space, in this case, was defined as any convex area bounded by at least three walls. An example of each type is shown in Figure 3.

Figure 3 A multiple-space diagram of a redundant-door solution (left) and a single-space diagram (right).

Participants who drew single-space diagrams were significantly more likely to produce analogous solutions to the pole problem than those who drew multiple-space diagrams. Of the 131 participants drawing redundant-door diagrams 26 drew single-space diagrams, and of those 12 (46%) produced analogous solutions to the pole problem. By contrast, only 10 of the 105 (10%) participants who drew multiple-space diagrams produced analogous solutions. The percentage of participants who produced analogous solutions to the pole problem in each of the two main configuration types is listed in Table 1.

Participants who drew diagrams in plan were also much more likely to produce analogous solutions to the pole problem than those who drew diagrams from other views. Of the 131 participants who drew redundant-door diagrams, 58 drew diagrams in plan, 14 (24%) of whom went on to produce an analogous solution to the pole problem. Of the 73 who drew redundant-door diagrams from other views, only 8 (11%) produced analogous solutions. The percentage of participants who produced analogous solutions to the pole problem in each view is listed in Table 2.

Table 1 Number of redundant-door diagrams drawn in each configuration type, and the percentage of those followed by an analogous solution to the pole problem.

	N	Analogous solutions
Single-space	26	46%
Multiple-space	105	10%
N	131	17%

Table 2 Number of redundant-door diagrams drawn in each view, and the percentage of those followed by an analogous solution to the pole problem.

	N	Analogous solutions
Plan	58	24%
Elevation	42	10%
Perspective	22	9%
Ambiguous	9	22%
N	131	17%

There are at least two explanations for why participants were less likely to produce analogous solutions to the pole problem when drawing multiple-space diagrams than when drawing single-space diagrams. One is that additional spaces meant that there were additional unalignable features in the source that could have interfered with a successful mapping. Although this possibility is hard to assess, it should be noted that there were a number of other randomly distributed unalignable features in the diagrams that could have countervailed those associated with multiple spaces.

A second explanation, and one that is more in line with our original hypothesis, is that additional spaces made it more difficult to transform a perceptual simulation of a redundant-door solution into a perceptual simulation of a redundant-pole solution. This explanation rests on three assumptions: first, that the diagrams scaffolded simulations of physical objects with particular transformational affordances; second, that using a redundant-door solution to solve the pole problem required imagining the door system in motion; and third, that a simulated door system might have been rooted via a kinesthetic sense of inertia that would make it difficult to imagine motion. If so, whether a redundant-door diagram facilitated the production of an analogy would have depended on the diagram's affordances. Specifically, the depiction of additional spaces could have caused the door system to seem more physically encumbered and hence harder to simulate in motion as required for a successful mapping.

The fact that view was also correlated with the production of analogous solutions to the pole problem further supports the idea that diagrams both scaffolded and constrained perceptual simulations. Participants, for example, would have likely been able to visualize doors swinging open more easily in plan than in other views (the motion being orthogonal to such a view), making it easier to simulate the actions needed to solve the pole problem. In addition, plan-view simulations may have been more easily transformed because they were not constrained by gravitational affordances, gravity being orthogonal to spatial relations depicted in plan view (Franklin and Tversky, 1990; Rock, 1973). The idea that view and configuration may have influenced perceptually simulated transformations is, of course, speculative. The next two experiments attempt to provide more support for the claim.

Experiment 2

One of the findings from Experiment 1 was that the configuration of source diagrams was correlated with the production of analogous solutions to a target problem. We argued that the diagrams scaffolded perceptual simulations, which could have then been transformed to fit the physical context of the target problem if the diagrams afforded those transformations.

Although Experiment 1 helped illustrate this argument, the analysis was primarily post hoc. The experiment discussed in this section is designed to test the claim in a more controlled way.

A two-condition variation of Experiment 1 was designed. Participants in both conditions were given the door problem with a redundant-door solution already specified and a diagram illustrating it. They were then given the pole problem and asked to solve it, along with the hint that the solution to the door problem might help them. The independent variable was the type of diagram shown with the door problem, while the dependent variable was the type of solution participants produced for the pole problem.

In one condition (the afforded condition) participants were given a redundant-door diagram showing a door vestibule bisecting a wall bounding the lab. In the other condition (the unafforded condition) participants were given a diagram showing the same door vestibule abutting the wall (Figure 4). The number and type of elements were the same in both diagrams, ensuring that differences in performance could not be attributed to differences in the number or type of unalignable objects. Although both diagrams are single-space configurations according to the coding scheme used in Experiment 1, they differ in their physical affordances, particularly in how the vestibule is perceived in relation to the wall. In the afforded condition, the wall and the vestibule are meant to be perceived as overlapping, following the Gestalt law of continuation. In the unafforded condition, by contrast, the vestibule is meant to be seen as resting up against, or attached to, the wall. The diagram in the unafforded condition should thus be harder to imagine moving because it is encumbered by (or anchored to) the lab space, in turn making it harder to align with the pole problem. Following this reasoning, we predicted that participants in the unafforded condition would be less likely to produce an analogous solution to the pole problem than those in the afforded condition.

Figure 4 Diagrams used in the afforded condition (left) and the unafforded condition (right) of Experiment 2.

Materials and Procedure

The door problem and the pole problem used in Experiment 1 were printed on a single sheet of paper. Just below the door problem was written, "Have workers enter a vestibule space before entering the lab," along with one of the two diagrams shown in Figure 4,

depending on the condition. Instructions printed at the top of the page and just below the two problems asked participants to carefully read them and write down a solution to the second one. Participants were given 7 minutes to complete the task.

Participants

Twenty-eight students enrolled in undergraduate psychology classes at Georgia Tech participated in groups of 2 to 6 each, 14 in the afforded condition and 14 in the unafforded condition. All received class credit for participating.

Results and Discussion

Solutions to the pole problem were categorized as either analogous or non-analogous to the door problem using the criteria established in Experiment 1. Of the 14 participants in the afforded condition, 10 (71%) produced analogous solutions, compared to only 5 of 14 participants (36%) in the unafforded condition. As predicted, configuration was a significant predictor of whether participants produced analogous solutions ($\chi^2=3.82, p<.05$). The results are shown in Table 3.

Table 3 Participants producing analogous solutions to the pole problem in Experiment 2.

	Analogous solutions	N
Afforded diagram	71%	14
Unafforded diagram	36%	14

Experiment 3

Another notable finding in Experiment 1 was that participants who drew plan diagrams were more likely than those who drew diagrams from other views to produce analogous solutions to the pole problem. We argued that it was easier to perceptually simulate doors opening in plan and hence easier to simulate the action required to solve the pole problem. We also argued that it might be easier to transform a simulation of a redundant-door solution if the simulation was not perceptually structured in relation to gravity, or, in other words, if all spatial relations were orthogonal to gravity. To test this claim, we repeated Experiment 2 with two new redundant-door diagrams: one drawn from the side (unafforded condition) and one drawn from above (afforded condition) (Figure 5). Consistent with the arguments put forth in Experiment 1, we predicted that participants in the afforded condition would be more likely to produce an analogous solution to the pole problem.

Figure 5 Diagrams used in the afforded condition (left) and unafforded condition (right) of Experiment 3.

Materials and Procedure

The same materials and procedure used in Experiment 2 were used except that the diagrams accompanying the redundant-door solution were either elevation or plan diagrams, depending on the condition (Figure 5).

Participants

Twenty-two students enrolled in undergraduate psychology classes at Georgia Tech participated in groups of 2 to 6 each, 11 in the afforded condition and 11 in the unafforded condition. All received class credit for participating.

Results and Discussion

Solutions to the pole problem were categorized as either analogous or non-analogous to the door problem, using the criteria established in Experiment 1. Of the 11 participants in the afforded condition, 7 (64%) produced analogous solutions, compared to only 2 of the 11 participants (18%) in the unafforded condition. Consistent with our prediction, diagram view was thus a significant predictor of whether participants produced analogous solutions ($\chi^2=5.43$, $p<.05$). The results are shown in Table 4.

Table 4 Participants producing analogous solutions to the pole problem in Experiment 3.

	Analogous solutions	N
Afforded diagram	64%	11
Unafforded diagram	18%	11

Conclusions

The studies reported here begin to shed light on what might make a diagram useful for constructing an analogy. They results strongly suggest that aspects of diagrams like view and configuration can influence the ease with which diagrammed solutions can be used to solve analogous problems, possibly by regulating simulated transformations. The studies also lend support to the more general idea that analogies can be constructed via perceptual simulations, as opposed to predicate-based, or otherwise perceptually neutral, representations. And finally, although just a start, the results reported here help illustrate an expanded role for drawings as cognitive tools. Drawings might now be seen not only as a means for recording ideas for future reference but also as a means for exploring the transformational affordances of problem spaces in search for those that will ultimately lead to more promising solution paths. Problem solvers might, from this point of view, actually learn to manipulate problem spaces via diagrammatic affordances just as they might learn to navigate problem spaces using conventional reasoning strategies.

Abstract

In this paper we discuss a generic component of a cognitive agent architecture that merges beliefs, obligations, intentions and desires into goals. The output of belief, obligation, intention and desire components may conflict and the way the conflicts are resolved determines the type of the agent. For component based cognitive agents, we introduce an alternative classification of agent types based on the order of output generation among components. This ordering determines the type of agents. Given four components, there are 24 distinct total orders and 144 distinct partial orders of output generation. These orders of output generation provide the space of possible types for the suggested component based cognitive agents. Some of these agent types correspond to well-known agent types such as realistic, social, and selfish, but most of them are new characterizing specific types of cognitive agents.

Introduction

Imagine an agent who is obliged to settle his debt, desires to go on holiday, and intends to attend a conference. Suppose that he believes he can only afford to finance one of these activities and decides to pay his checks to settle his debt. Unfortunately, our agent does not earn much money and is in the habit of buying expensive books. Therefore, he runs again into debt after a short while. Despite the fact that he still has the same obligation, desire, and intention and believes that he can only afford to finance one of these activities, he decides this time to attend the conference. Directly after this decision, he hears that the conference is cancelled and he receives a telephone call from his mother telling him that she is willing to pay his checks for this time. The agent is now happy and decides to go on holiday. Our agent has a friend who has the same obligation, desire, and intention, and likewise believes that he can only afford to finance one of these activities. In contrast to our agent, this friend decides to go on holiday. However, he is late with arranging his holiday; all travel agencies are sold out. Therefore, he decides to attend the conference. In a different situation where these two agents are obliged to visit their mothers, desire to go to cinema, and believe they cannot do both simultaneously, the first agent decides to visit

his mother while his friend goes to cinema. Yet in another situation where these agents intend to clean up their houses, are obliged to help their friends, and believe they cannot do both, they decide to clean up their houses. Although these agents behave differently, each of them seems to follow a certain behavior pattern under different situations. The first agent seems to be more sensitive to his intentions and obligations than to his desires while the second agent seems to prefer his desires more than his intentions and obligations. Moreover, the first agent seems to be indifferent towards his intentions and obligations while the second agent seems to prefer his intentions above his obligations. These characteristics and principles that govern agent's actions and behavior determine the type of cognitive agents and can be used as the basis for a classification of cognitive agents.

We are motivated by the studies of cognitive agents where the behavior of an agent is defined in terms of rational balance between its mental attitudes [1, 9, 5]. A classification of cognitive agent types specifies possible ways to define the rational balance. Beside the scientific need to study possible definitions of rational balance in a systematic way, a classification of cognitive agent types is important for many applications where it is impossible to specify agent behavior in specific and usually unknown situations. In such applications, it is important to specify the behavior of agents in strategic terms and by means of types of behavior.

In [2] we investigate the design and implementation issues of generic component-based cognitive agents. In the present paper, we propose an alternative classification of cognitive agent types. There has been many formal and informal studies proposing agent types [1, 8, 4]. In these studies, there is a trade-off between the space of possible agent types and their precise and formal definitions. In particular, informal studies provide a rich space of possible types of cognitive agents and ignore their precise definitions, while formal studies provide precise definition of agent types but ignore the richness of the space of possible types. The proposed classification of cognitive agent types in this paper is formal and in terms of a generic component based architecture.

This classification is systematic and provides a large space of possible types for cognitive agents. Some of these agent types such as realistic, social, and selfish are well-known. However, most of these agent types are new and characterize specific types of behavior.

The layout of this paper is as follows. First, we discuss different ways of classifying agent types. Since our classification is based on generic component based agent architecture, we briefly discuss this architecture and explain some of its properties that are relevant for the agent type classification. Possible agent types within this architecture are discussed. An example of a conflict situation is formalized and it is shown how different agent types behave differently in this situation. Finally, we conclude the paper and indicate future research directions.

Classification based on Agent Architecture

Various frameworks with corresponding type classifications for cognitive agents are proposed [9, 5, 3]. Considering different phases in agent oriented software development process such as analysis, design, and implementation phases, most proposed cognitive agent frameworks with corresponding type classifications are provided for the analysis phase. For example, Rao and Georgeff's BDI framework with realism and commitment strategies as agents types [9] have been developed as formal specification tools for the analysis phase. In this framework, the single minded agent type is thought to be the one which maintains its commitments until either it believes it has fulfilled its commitments or it does not believe it can ever fulfill its commitments.

Although these formal tools and concepts are very useful to specify various types of cognitive agents, they are specifically developed for the analysis phase which makes them too abstract for other phases. In fact, to design and to implement various types of cognitive agents, we need to define agent types in terms of tools and concepts available at the design and the implementation phases such that they can be translated into agent architectures and agent implementations. A closer look at the specification formalisms such as Rao and Georgeff's BDICTL formalism shows that the space of theoretically possible cognitive agent types is determined by the expressive power of that formalism. Obviously, other phases of agent development process restrict and narrow down the space of possible agent types since available concepts and tools at those phases should satisfy conditions such as realizability and computability. This implies that each agent architecture allows only a subset of possible agent types that can be specified at the analysis phase. Therefore, it is essential for each agent architecture to indicate which types of agents can be designed in that architecture. The classification of cognitive agent types in this paper

is proposed for the design phase and it is thus in terms of agent architecture.

Agent Architecture

In general, agent architectures are defined in terms of knowledge representation (i.e. data) and reasoning mechanism (i.e. control). The agent type classification, which we introduce in the next section, is defined in terms of properties of generic component based architecture called BOID (BOID stands for Beliefs, Obligations, Intention, and Desire). Therefore, we first briefly explain this architecture, which can be seen as a black box with observations as input and intended actions as output. The architecture and the logic of BOID are discussed in more detail elsewhere [2].

A BOID agent observes the environment and reacts to it by means of detectors and effectors, respectively. Each component in the BOID architecture is a process having an input and output behavior. For this reason and to model the input/output behavior of each component, the components are abstracted as a rule-based systems that contains a set of defeasible rules. As these components output mental attitude only for certain inputs, they represent *conditional* mental attitudes. In the BOID architecture two modules are distinguished: the goal generation module and the plan generation module. The goal generation module generates goals based on beliefs, desires, intentions and obligations, and the plan generation module generates sequences of actions based on these goals. In the rest of this paper, we focus only on the goal generation module since the presented classification of the agent types is defined in terms of rational balance between agent's mental attitudes. Possible classification of agent types that can be defined in terms of the plan generation module or in terms of the interaction between the goal or the plan generation modules are out of the scope of this paper.

The BOID architecture differs from the Procedural Reasoning System (PRS) [7], which is developed within the BDI (Beliefs, Desires, and Intention) framework, in several aspects. The first difference is that BOID extends PRS with obligations as an additional component. One reason for this extension is to incorporate elements of the social level, i.e. social commitments, to formalize for example social agents and social rationality. The second difference is related to the conditional nature of mental attitudes in BOID. In fact, each mental attitude is abstracted as a rule-based system containing defeasible rules. This is in contrast with the representation of mental attitudes in PRS which are sets or lists of formula. The third difference is that the BOID components, which represent mental attitudes, are processes having their own control mechanism. Thus, in contrast to the central control mechanism in PRS, in BOID there are two levels of controls. A central control

mechanism at the agent level coordinates activities among components. The control mechanism at the component level determines how and which output is generated by each component when it receives input. Finally, the goals in BOID are generated by the interactions between agent's mental attitudes in contrast to the PRS where goals are given beforehand and become selected by the central control mechanism.

As noticed, each component can be abstracted as a rule-based system specified by propositional logical formulas, in the form of defeasible rules represented as $a \hookrightarrow b$. The reading of a rule depends on the component in which it occurs. For example, a rule in the obligation component, represented as $a \xrightarrow{O} b$, should be read as follows: if a is derived as a goal and it is not inconsistent to derive b , then b is obliged to be a goal. The input and the output of components are represented by sets of logical formulas, closed under logical consequence. Following Thomason [10] these are called *extensions*. The logic that specifies extensions is based on prioritized default logic that takes an ordering function ρ as parameter. This function constraints the order of derivation steps for different components and characterizes the type of the agent. We first briefly discuss the BOID conflict resolution mechanism and then explain how the ordering function can be used to define various agent types.

Conflict Resolution Mechanism

In the BOID architecture, goals are generated by a calculation mechanism. The calculation starts with a set of observations Obs , which cannot be overridden, and initial sets of default rules for the other components: B, O, I, D . Moreover, it assumes an ordering function ρ on the rules of the different components. The procedure then determines a sequence of sets of extensions S_0, S_1, \dots . The first element in the sequence is the set of observations: $S_0 = \{Obs\}$. A set of extensions S_{i+1} is calculated from a set of extensions S_i by checking for each extension E in S_i whether there are rules that can extend the extension. There can be none, in which case nothing happens. Otherwise each of the consequents of the applicable rules with highest ρ -value are added to the extension separately, to form distinct extensions in S_{i+1} . The operator $Th(S)$ refers to the logical closure of S , and the syntactic operation $Lit(b)$ extracts the set of literals from a conjunction of literals b . In practice not the whole set of extensions is calculated, but only those that are calculated before the agent runs out of resources.

Definition 1 A tuple $\Delta = \langle Obs, B, O, I, D, \rho \rangle$ is called a *BOID theory*. Let L be a propositional logic, and an extension E be a set of L literals (an atom or the negation of an atom). We say that:

- a rule $(a \hookrightarrow b)$ is *strictly applicable* to an extension E , iff $a \in Th(E)$, $b \notin Th(E)$ and $\neg b \notin Th(E)$;

- $\max(E, \Delta) \subseteq B \cup O \cup I \cup D$ is the set of rules $(a \hookrightarrow b) \in \max(E, \Delta)$ strictly applicable to E such that there does not exist a $(c \hookrightarrow d) \in B \cup O \cup I \cup D$ strictly applicable to E with $\rho(c \hookrightarrow d) > \rho(a \hookrightarrow b)$;
- $E \subseteq L$ is an *extension* for Δ iff $E \in S_n$ and $S_n = S_{n+1}$ for the procedure in Figure 1.

```

i := 0; Si := {Obs};
repeat
  Si+1 := ∅;
  for all E ∈ Si do
    if exists (a ↪ b) ∈ B ∪ O ∪ I ∪ D strictly
      applicable to E then
      for all (a ↪ b) ∈ max(E, Δ) do
        Si+1 := Si+1 ∪ { E ∪ Lit(w) };
      end for
    else
      Si+1 := Si+1 ∪ {E};
    end if
  end for
  i := i + 1;
until Si = Si-1;

```

Figure 1: Procedure to calculate extensions

In our model, ρ can assign values to the rules, such that all rules from one component receive either larger or smaller values than the rules from another component. This implies that the rules from one components are applied before the rules from another component can be applied. This is the basis of our idea to define agent types. Of course, in many practical applications ρ must be specified further. For example, an agent may prefer some of his O rules to some of his D rules while conversely preferring some other D rules to some other O rules. However, this does not mean that our basic idea has to be dropped. It just means that the number of components has to be further specified and the ρ function has to be defined accordingly. Each component can thus be subdivided in a number of subcomponents such that the ρ can describe the preference of the rules accordingly. Here we do not further describe this division since it is not important for the general idea of agent type classification that we present in this paper.

The parameter ρ may assign unique values to the rules of all components. In such a case, the BOID calculation scheme can apply in each iteration loop only one rule, which implies that the BOID calculation scheme generates only one extension. However, ρ may also assign identical integers to different rules. In this case, ρ imposes a partial ordering among the rules. For such a ρ , the above BOID calculation scheme can apply more than one rule in each iteration loop, which implies that the BOID calculation

scheme may generate a set of extensions. For example, consider a scenario in which an agent believes that he is in a non-smoking area (i.e. $\top \xrightarrow{B} nsa$). He intends to smoke (i.e. $\top \xrightarrow{I} s$), but he intends not to smoke when he is in a non-smoking area (i.e. $nsa \xrightarrow{I} \neg s$). Define ρ as follows:

$$\rho(\top \xrightarrow{B} nsa) > \rho(nsa \xrightarrow{I} \neg s) > \rho(\top \xrightarrow{I} s)$$

For this ρ , the BOID calculation scheme as defined in Definition 1 generates one single extension which is: $\{nsa, \neg s\}$.

Now, suppose ρ is defined as follows:

$$\rho(\top \xrightarrow{B} nsa) > \rho(nsa \xrightarrow{I} \neg s) = \rho(\top \xrightarrow{I} s)$$

This ρ does assign identical integers to the intention rules and the BOID calculation scheme generates the following two extensions: $\{nsa, \neg s\}$ and $\{nsa, s\}$.

Agent Types

Given the presentation of mental attitudes and the BOID calculation scheme, we investigate which type of interactions between mental attitudes can arise within the BOID architecture and how these interactions can be classified. In principle, there are fifteen types of conflicts that can occur between the mentioned four mental attitudes [2]. These conflicts can be solved in different ways. We explain how different ways of resolving conflicts can be modelled by restricting the order of rule application in the BOID calculation scheme. We argue that these restrictions specify different types of the BOID agent and introduce a classification of the types for the BOID agents. Finally, some examples of BOID types and their solutions to one and the same conflict situation is presented.

Conflict resolution and agent types

One of the main tasks of deliberative agents is to solve possible conflicts among their mental attitudes. In principle, there are fifteen different types of conflicts that may arise either within each class or between classes. Dependent on the exact interpretation of these classes, some of the conflict types may be more interesting or important than others. We distinguish two general types of conflicts: internal and external conflicts. *Internal conflicts* are caused within each component while *external conflicts* are caused between them. Internal conflicts can be distinguished into four unary subtypes (B ; O ; I ; D). External conflicts can be distinguished into six binary conflict subtypes (BO ; BI ; BD ; OI ; OD ; ID), and four ternary conflict types (BOI ; BOD ; BID ; OID) and one quadruplicate conflict type (BOID). An example of the BOID external conflict type is the following situation: *The agent intends to go to*

a conference. It is obligatory for the agent not to spend too much money for the conference. In particular, either the agent should pay for a cheap flight ticket and stay in a better hotel, or the agent should pay for an expensive flight ticket and stay in a budget hotel. The agent desires to stay in a better hotel. But, he believes that the secretary has booked an expensive flight ticket for him. More examples of these conflicts are presented in [2].

A conflict resolution type, which characterizes an agent type, is considered here as an order of overruling. Given four components in the goal generation module of the BOID architecture, there are 24 possible orders of overruling. In this paper, we only consider those orders according to which the belief component overrules any other component. This reduces the number of possible overruling orders to 6. Some examples of conflict resolution with beliefs are as follows. A conflict between a belief and an intention means that an intended action can no longer be executed due to the changing environment. Beliefs therefore overrule the intention, which is retracted. Any derived consequences of this intention are retracted too. Of course, one may allow intentions to overrule beliefs, but this results in unrealistic behavior. Conflicts between beliefs and obligations or desires need to be resolved as well. As observed by Thomason [10], the beliefs must override the desires or otherwise there is wishful thinking. Moreover, a conflict between an intention and an obligation or desire means that you now should or want to do something else than you intended before. Here intentions override the latter because it is exactly this property for which intentions have been introduced: to bring stability [1]. Only in a call for intention reconsideration such conflicts may be resolved otherwise. For example, if I intend to go to cinema but I am obliged to visit my mother, then I go to cinema unless I reconsider my intentions.

Using the order of string letters as the overruling order and thus as representing the agent type, a realistic agent can have any of the following six specific agent types, i.e. BOID, BODI, BDIO, BDOI, BIOD, and BIDO. These specific agent types are not known in the literature and we do not have any name for them. Note that we overloaded the name BOID in this way, because it becomes a specific type of agent as well as the general name for the agent architecture. These six specific agent types, in which beliefs override all other components, can be represented as a constraint on the ρ function resulting in the well-known agent type, called *realistic*.

Definition 2 *Realistic agent type is a constraint on the ρ function formulated as follows:*

$$\forall r_b \in B, r_o \in O, r_i \in I, r_d \in D \\ (\rho(r_b) > \rho(r_o) \wedge \rho(r_b) > \rho(r_i) \wedge \rho(r_b) > \rho(r_d)) \\ \text{or simply}$$

$$B \succ O \wedge B \succ I \wedge B \succ D$$

Now that we have a specific ρ function that characterizes realistic BOID types, we indicate how the extension is calculated. Following definition 1, a realistic BOID agent starts with the observations and calculates belief extensions by iteratively applying belief rules. When no belief rule is applicable anymore, then either the O , the I , or the D component is chosen from which one applicable rule is selected and applied. When a rule from a chosen component is applied successfully, the belief component is attended again and belief rules are applied. If there is no rule from the chosen component applicable, then another component is chosen again. If there is no rule from any of the components applicable, then the process terminates – a fixed point is reached – and extensions are calculated.

Other agent types can be specified as constraints on the ρ function as well. Since we consider in this paper only realistic agent types, we limit ourselves to those agent types that are subtypes of realistic agent types. Some of well-known agent types can now be represented as follows.

BIDO, BOID, and BIOD are called *stable*, because intentions overrule desires, i.e.

$$B \succ O \wedge B \succ I \wedge B \succ D \wedge I \succ D$$

BDIO, BIDO, and BDOI are called *selfish*, because desires overrule intentions, i.e.

$$B \succ O \wedge B \succ I \wedge B \succ D \wedge D \succ O$$

BOID, BIOD, and BODI are called *social*, because obligations overrule desires, i.e.

$$B \succ O \wedge B \succ I \wedge B \succ D \wedge O \succ D$$

The six specific realistic agent types mentioned earlier are subtypes of these three well-known more general realistic agent types. Other agent types, for which we do not have any name, are still possible. The relation between these and other realistic agent types forms a lattice illustrated in Figure 2. The level in this hierarchy indicates the generality of agent types. The bottom of this lattice is the realistic agent type that is characterized by the least number of constraints on the ρ function. Each higher layer adds additional constraints resulting in more specific agent types. At the second level, the stable, social, and selfish agent types result, and at the fourth level the mentioned six specific and unknown agent types (BIDO, BIOD, BDIO, BDOI, BOID, and BODI) result. The top of this lattice is the falsum, which indicates that adding any additional constraint to the ρ function results in an inconsistent ordering.

Example

In this section, we illustrate how conflicts between mental attitudes can be solved within the BOID

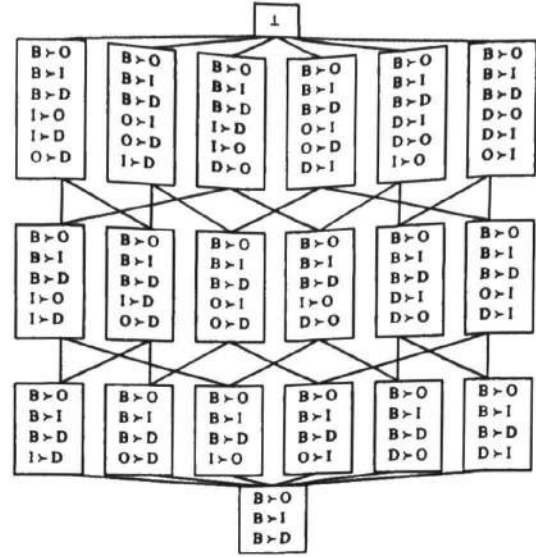

Figure 2: The lattice structure of agent types.

architecture by giving an example that describes the following mental attitudes: *If I go to Washington DC (Go2DC), then I believe that there are no cheap rooms (ChRm) close to the conference site (Close2ConfSite). If I go to Washington DC, then I am obliged to take a cheap room. If I go to Washington DC, then I desire to stay close to the conference site. I intend to go to Washington DC.* This example can be represented by the following rules:

$$\begin{aligned} \rho = 5 & \quad (Go2DC \wedge ChRm) \xrightarrow{B} \neg Close2ConfSite \\ \rho = 4 & \quad (Go2DC \wedge Close2ConfSite) \xrightarrow{B} \neg ChRm \\ \rho = 3 & \quad Go2DC \xrightarrow{D} Close2ConfSite \\ \rho = 2 & \quad Go2DC \xrightarrow{O} ChRm \\ \rho = 1 & \quad \top \xrightarrow{I} Go2DC \end{aligned}$$

Lets examine a specific type of social agent, i.e. BIOD. Let the input of the agent be empty. Then, following the extension calculation mechanism, we first derive all beliefs and intentions, resulting in the following extension:

$$\{Go2DC\}$$

Because it is a social agent (i.e. the fourth rule has a higher priority than the fifth rule), the obligation rule is applied first. This results in the following intermediate extension:

$$\{Go2DC, ChRm\}$$

This extension is fed back into the B component where it triggers the first belief rule (i.e. the first

rule), because the second belief rules is not applicable as we already have ChRm. This produces the following final extension:

$\{Go2DC, ChRm, \neg Close2ConfSite\}$

This extension denotes the situation in which the agent has decided to go to Washington DC and takes a cheap room not close to the conference site, which is indeed social behavior.

However, if we exchange the priority of the fourth and the fifth rules the agent becomes a selfish agent 'BIDO'. Then, the *D*-rule would be applied before any obligation rule is applied, resulting in the following final extension:

$\{Go2DC, \neg ChRm, Close2ConfSite\}$

Sending the results back to the belief component does not make any difference here. This extension denotes the situation in which an agent has decided to go to Washington DC and takes an expensive room close to the conference site, which is indeed selfish behavior.

Concluding Remarks

We have briefly discussed the generic component based BOID architecture that is developed for cognitive agents. Each component in the BOID architecture represents a mental attitudes of the agent. The output of components may conflict. Some of the conflicts that may arise among BOID's components are presented. In the BOID architecture the conflicts are resolved by the order of output generation from different components. We have shown that the order of output generation determines the type of an agent. In general, the order of output generation can be used to identify different types of agents. We have shown that these conflict resolution mechanisms provide some well-known agent types and an interesting set of unknown agent types. In particular, we have shown that for a realistic agent beliefs are generated before obligations, intentions or desires; for a stable agent intentions are generated before desires; and for selfish agents desires are generated before intentions.

We believe that the way the BOID components are updated depends also on the type of the agent. The integration of updating various components have the highest priority in our research agenda. Another issue which in on our future research agenda is the incorporation of agent types derived from plan generation module and its interaction with goal generation modules. In the BOID architecture, the plan generation module influences the computation of extensions and therefore may play an important role in agent type classification. For example, when a generated extension cannot be transformed into a sequence of actions, another extension should be selected. The exact choice for a new extension should depends on the type of agent as well.

Abstract

The relationship between theoretically-grounded hints, strategy selection, and solution performance in the Toads and Frogs puzzle, a well-structured problem in which weak methods are difficult to apply, is investigated through an experiment and an ACT-R simulation. The main results show that providing a state specific hint is useful in speeding up the adoption of a hybrid solution strategy, comprising both the retrieval of previous moves and the proceduralization of a domain-specific heuristic that avoids any kind of forward search. The implications of the results for the problem solving theory are discussed.

Introduction

Research work on problem solving has attained to significant success in identifying the sources of difficulty for several kinds of well-structured problems (Newell & Simon, 1972). Working memory limitations (Miyake & Shah, 1999), in particular, play a prominent role in explaining why some problems are “so hard”, and many factors have been identified that affect the working memory load. A partial list comprises the execution of legality tests on the operators (Kotovsky, Hayes & Simon, 1985), the number of options to be considered, and the availability of useful external memories (Cary & Carlson, 2001; Zhang & Norman, 1994).

Independently from working memory limitations, problem solvers seem reluctant to engage in a high degree of forward planning (Atwood, Masson & Polson, 1980; Ward & Allport, 1997; Simon & Reed, 1976). People usually recur to heuristic strategies, often relying on weak methods such as hill-climbing or means-ends analysis (Anderson, 1982; Anzai & Simon, 1979; Simon, 1975; Simon & Reed, 1976), and take into account only a limited number of states.

It is however interesting to wonder what strategy would be used in problems requiring a substantial degree of search when weak methods are not directly applicable. Here we try to answer this question by carrying out a first empirical exploration of problem solving behavior in a new kind of task.

First, we introduce the *Toads and Frogs* puzzle (henceforth T&F), a problem we found particularly suitable for the present research because of the peculiar structure of its problem space. We describe then a set of candidate strategies for solving it, and present an experiment designed to study the effectiveness of two types of hints delivered through the interface. Next we summarize the results of an ACT-R simulation aimed at identifying the strategies actually used by participants, and at tracing their development. Finally, we discuss the findings in the light of two main classes of problem solving strategies (memory-based vs. rule-based).

The Toads and Frogs Puzzle

The T&F puzzle (Berlekamp, Conway & Guy, 2001) is a well-structured problem that, to the best of our knowledge, has never been previously utilized in psychological research.

In the variant used here, three toads are placed on the three leftmost squares of a seven-square board while three frogs are placed on the three rightmost squares (Figure 1). The central square is initially empty. The goal of the game is to switch the animals' positions by having the toads occupy the three rightmost, and the frogs the three leftmost squares, respectively. A square can be occupied by only an animal at a time, and an animal can move only into the empty square. Toads can move only rightward and frogs only leftward. There are two possible types of move: a Slide to the next (empty) square and a Jump over an animal of a different type to a two-square apart empty position. A solution can be reached in exactly 16 moves, 9 Jumps and 7 Slides. Two symmetrical solution paths are possible, depending on the animal that is moved first (the solution sequence for the frog-move-first type of problem is presented in Figure 1).

Some of the moves in the solution path are forced (Jump only or Slide only) while in the remaining cases it is necessary to choose between two Slides, or between a Jump and a Slide, or between two Jumps (off the solution path only). Excluding the first move that allows two possible options, there exists a single right move for every

solution step, and it is not possible to retract a move when it has been done.

Figure 1: The Toads and Frogs problem

From a normative point of view, it is possible to identify two rules that foster the T&F puzzle solution. First, in deciding between two Slides, avoid the move that brings to a fatal Jump-Jump configuration, i.e., a state in which both legal moves are Jumps (an example is given in Figure 1). Every such configuration lies off the solution path and leads eventually to a dead end. Second, in choosing between a Jump and a Slide, select the Jump.

From a psychological viewpoint, the problem presents some interesting properties. It cannot be solved through hill-climbing, because this strategy does not help in deciding what to do when facing the critical Slide-Slide choices. A pure forward planning approach will not work either, because detecting dead ends would require an unattainable degree of look-ahead. The problem is also hard to solve by means-ends analysis, because of the difficulty to find out useful subgoals. The natural subgoal choice (i.e. putting the most advanced animal to its target location) cannot be used in the first solution steps due to the necessity to plan up to seven moves and to detect ten potential dead-ends. Finally, it is unlikely to find the solution by pure chance ($p=0.0039$).

Candidate Problem Solving Strategies

From the analysis of some concurrent verbal protocols collected in a pilot study and by combing the problem solving literature, we were able to define a set of candidate solution strategies for the T&F puzzle. We will briefly present the strategies and the hypotheses about the performance measure that can be derived from them.

AVOID BLOCKS (AB) This strategy can be reduced to two rules: (1) Avoid moves that bring to a "blocked" state. A state is considered blocked whenever the moved

animal is preceded in its moving direction by an animal of the same type that (a) cannot be moved, and (b) is not placed in its final position. (2) In cases when none of the two legal moves brings to a blocked state, choose randomly between them. This strategy reflects the general heuristic of avoiding bad states, and it hypothesizes chance-level performance in the Slide-Slide choices.

JUMP AND RANDOM (JRND) In the Jump-Slide choices always select a Jump move. In the Slide-Slide choices choose randomly. The "always Jump" rule could be acquired by proceduralizing the hill-climbing heuristic. The strategy predicts a higher error rate in the Slide-Slide decisions in comparison with the Slide-Jump ones.

MOVE PATTERN (MP) Because the sequence of moves to reach the solution is highly patterned, implicitly learn to perform the pattern of moves. For instance, when the first move is the Slide of the most advanced frog [F1], the solution pattern is: [F1] T1 T2 F1 F2 F3 T1 T2 T3 F1 F2 F3 [T2 T3 F3] with the three final moves being on-the-target moves. This strategy (described, among others, by Reber & Kotovsky, 1997) predicts an approximately similar percentage of errors for each class of choices and no difference in the associated decision times.

JUMP AND RETRIEVE (JR) In the Jump-Slide choices, always select a Jump move. In the Slide-Slide choices, try to retrieve the last decision taken in the same situation, using the current state as a memory cue. If the last trial is remembered as a success, repeat the retrieved move, else select the alternative legal move. The strategy constitutes a partial version of the trial-and-error weak method. It predicts higher times (due to retrieval costs) and higher error rates (due to retrieval errors) in the Slide-Slide choices than in the Slide-Jump ones.

JUMP AND SPACE (JS) Always Jump in the Jump-Slide pick. In the Slide-Slide choices, select the move that brings to a state in which there is exactly one interposed square between each neighboring pair of animals like the moved one. This rule implements a domain-specific preference for states in which animals of the same type are regularly spaced. The strategy stems from the verbal protocols of participants stating their desire to reach an "alternating sequence" of animals. They claimed they wanted "to make some space" between the animals of the same type to allow the possibility for the other animals to "jump into". The strategy could be acquired by a perceptual noticing mechanism (Ruiz & Newell, 1989) and by the use of the perceived features as subgoals within a means-ends approach (Anzai & Simon, 1979). It requires: (a) to imagine a state stemming from the execution of a move; (b) to maintain the imagined state in working memory; (c) to perform two distance tests on the imagined state; (d) to select the right move depending on the test outcome. This process is time expensive and can be error-prone, therefore the strategy predicts higher times and error rates in the Slide-Slide decisions than in the Slide-Jump ones.

The Experiment

We performed an experiment to analyze the effect of two interface hints on the performance in the T&F puzzle, and on the acquisition of the solution strategies.

The first hint is motivated by the work of Kotovsky, Hayes & Simon (1985), who suggested that the execution of legality tests on the operators constitutes a major source of difficulty in the Tower of Hanoi isomorphs (the so-called rule-application hypothesis). According to the authors, the working memory load associated with these tests initially hinders the discovery of a solution strategy. Assuming that legality tests could be a source of difficulty also in the T&F problem, we devised an interface hint that completely removes any cost associated with their execution. With the "legality hint" enabled, the movable tokens pop out in the interface, being displayed on squares of a different color. In this way the legality tests are embedded into the interface. This manipulation should free working memory resources, and make them available for problem solving and for the acquisition of a solution strategy.

The second hint is related to the structure of the problem space and, in particular, to our hypothesis that the Slide-Slide choices are the biggest sources of difficulty in the T&F puzzle because they cannot be handled by the weak methods commonly used in problem solving. With the "state hint" enabled, an image pattern representing the common part of the fatal Jump-Jump states is presented in the State Hint Area of the User Interface Window (Figure 1) whenever participants face a Slide-Slide choice. The participants were instructed to avoid executing a move that will bring them in a state corresponding to the hint pattern. According to our hypothesis, the hint should be very effective in removing the main error source, and in helping participants to find a good decision policy in the Slide-Slide choices.

Finally, it is reasonable to expect a synergic interaction between the two kinds of hints, since the working memory unload provided by the first hint should enhance the effect of the state hint.

Method

Participants and Materials The participants were 72 undergraduates students, aged between 19 and 30. The sample was approximately balanced for gender. All the participants had a basic familiarity with computers, and were able to use the mouse. Two different versions of the T&F problem were used by having the first move (Slide a toad vs. Slide a frog) automatically generated by the computer. The first choice actually splits the problem space in two almost completely non-overlapping sub-spaces (there are only a few common states, placed off the solution paths).

Procedure Participants read an instruction document that explained the rules of the T&F, described the task, and showed how to use the interface. Depending on the experimental conditions, the document presented also the available hints. In order to decrease the likelihood of a random solution, we adopted as the learning criterion the attainment of the final state in two consecutive trials. The interface did not allow undoing a previously executed move. After getting stuck, or after a voluntary interruption of a trial, the solver should start again from the beginning. Participants were required to solve both versions of the problem in the order specified by the experimental design. They had allotted a maximum time of 20 min for the first problem and of 10 min for the second one. No limits were placed on the number of trials.

Apparatus A PowerMacintosh G3 was used for the experiment. A program implementing the T&F puzzle was written using MCL 4.3.1 and CLIM2. The program recorded each participant move and the associated time. The interface window was composed by two parts. The upper part was only used to display the state hint. The lower part showed the puzzle board and an "Interrupt" button. To move an animal, it was only required to click on the square containing it. If the move was allowed by the problem rules, the positions of the animal and of the blank square were immediately updated; in case of an illegal move, a warning sound was delivered.

Experimental Design Two between-subjects independent variables (State Hint and Legal Hint availability) were manipulated in a 2x2 factorial design. The 72 participants were randomly assigned to the four experimental groups. We adopted a transfer design, presenting the two different versions of the problem in a counterbalanced order. The hints were available only for the first problem, and the participants were made fully aware of this by the instructions and by the experimenter. The basic dependent variables for each problem were the achievement of the criterion, the total time, and the total number of trials needed to achieve it. More detailed dependent measures were the percentages of errors, and the mean move latency for each choice class.

Results

We will first present the results on the whole data to test the hypotheses about the effectiveness of the interface hints. Then we will report two series of results concerning the participants who reached the criterion in both the problems: the first to assess the transfer, the second to provide detailed performance analyses that will be compared with the predictions of the various strategies.

Hint Effectiveness

Criterion. Table 1 presents the frequency of problem solving outcomes for each hint group and problem.

Table 1: Frequency of problem solving outcomes.

GROUP	Total Failure	Criterion Problem 1 Only	Criterion Problem 2 Only	Criterion Problem 1 & 2
Control	5	0	6	7
Legal Hint	1	2	3	12
State Hint	1	2	0	15
Both Hints	3	4	2	9

In the first problem, a higher number of participants in each hint group reached the criterion in comparison with the control group (no hint). The Fisher Exact test showed significant differences between the control group and the Legal Hint group ($p=0.0205$), the State Hint group ($p=0.0005$) and the group with both hints ($p=0.0461$), respectively. No significant differences were found in the second problem. Contrasting the frequency of criterion attainment in both problems with the frequency of any other outcome, only the State Hint group resulted significantly better than the control group (Fisher Exact test, $p=0.0076$).

Times. A 2x2 ANOVA on the aggregate problem times yielded only the significant main effect of the State Hint ($F(1,68)=8.37$, $MSE=50.98$, $p<0.01$). The participants without the state hint had to devote more time to the problems (State Hint: $M=15.08$ min, No Hint: $M=19.95$ min).

Number of trials. A 2x2 ANOVA on the aggregate problem trials showed a significant interaction between State Hint and Legal Hint availability ($F(1,68)=4.78$, $MSE=216.65$, $p<0.05$). Only the main effect of the State Hint was significant ($F(1,68)=10.00$, $MSE=216.65$, $p<0.01$). The Tukey HSD test showed significant differences between the State Hint group and the control group ($p<0.01$) and between the State Hint group and the Legal Hint group ($p<0.05$). The State Hint group had the lowest mean ($M=15.89$), followed by the control group ($M=27$), the Legal Hint group ($M=30.39$), and the group with both hints ($M=34.44$).

Transfer

Times. We computed a 2x2 ANOVA (Problem x State Hint availability) on the problem solution times. The analysis showed a two-way interaction between Problem and State Hint ($F(1,41)=9.20$, $MSE=9.04$, $p<0.01$). The Unequal N Tukey HSD test underlined a significant difference between the participants with the state hint and those without it, but only in the first problem ($p<0.05$). In both the conditions, the time to criterion significantly decreased from the first to the second problem (State Hint: $n=24$, $M1=7.26$ min, $M2=4.56$ min, $p<0.05$; No Hint: $n=19$, $M1=10.85$ min, $M2=4.19$ min, $p<0.001$).

Number of trials. A 2x2 ANOVA (Problem x State Hint availability) showed a two-way interaction between

Problem and State Hint ($F(1,41)=9.96$, $MSE=25.86$, $p<0.01$). The Unequal N Tukey HSD test highlighted the significant difference between the participants with the state hint and those without it, again only in the first problem ($p<0.01$). Only in the condition without the state hint, the number of trials significantly decreased from the first to the second problem (State Hint: $n=24$, $M1=8.42$, $M2=8.12$; No Hint: $n=19$, $M1=16.63$, $M2=9.37$, $p<0.001$).

Detailed Performance The choices of each participant in the non-forced moves were categorized depending on their location: the first Slide-Slide choice (SS-1), the second Slide-Slide choice (SS-2), or a Jump-Slide decision point. Then, the percentage of errors for each choice point was computed, according to the participant's number of transitions for that state. Finally, given the low value of the percentages for each of the six Jump-Slide choices, an overall mean error percentage (JS-M) for each participant was computed.

Errors. A 2x2x2 ANOVA (State Hint availability x Problem x Error type) yielded a significant three-ways interaction ($F(2,82)=3.30$, $MSE=251.3$, $p<0.05$). There was no significant difference on the JS-M error percentage between the State Hint and No State Hint conditions and between the first and the second problem (Unequal N Tukey HSD test). The JS-M error percentages were significantly lower than the SS error percentages in each State Hint condition and problem (least significant difference: $p<0.05$; JS-M means between 2 and 0). The difference on the SS-1 error percentages between the State Hint and No State Hint conditions was significant only in the first problem ($M-h=18$, $M-nh=43$, $p<0.01$). A similar result was obtained for the SS-2 error percentages, but the difference only approached significance ($M-h=26$, $M-nh=47$, $p=0.059$). Some single sample t-tests, carried out to evaluate the null hypothesis that the error percentages of the SS choices were not different from random performance (50%), did not allow us to reject the hypothesis only in the condition without state hint of the first problem. In the other cases the percentages were significantly lower (least significant difference: $p<0.05$; means ranging from 18 to 35).

Move times. A 2x2x2 ANOVA (State Hint availability x Problem x Error type) on the mean move times, showed a significant three-ways interaction ($F(3,123)=7.28$, $MSE=17.57$, $p<0.001$). The analysis comprised also the two kinds of forced moves (Jump and Slide only) and used the aggregated SS decision times. There were significant differences between the first and the second problem, but only for the real choices. The Unequal N HSD test yielded the following results in the conditions with the state hint: $p<0.001$ for SS ($M1=10.40$ s, $M2=4.94$ s) and $p<0.001$ for SJ-M ($M1=5.68$ s, $M2=3.30$ s). In the conditions without state hint the results are analogous: $p<0.001$ for SS ($M1=7.06$ s, $M2=4.16$ s) and $p<0.001$ for SJ-M ($M1=5.23$ s, $M2=2.93$ s). For both problems, the SS times were significantly higher than the JS times (State

Hint: $p < 0.001$ and $p < 0.001$; No State Hint: $p < 0.001$ and $p < 0.05$). The JS times were significantly slower than the forced moves ($p < 0.001$ for each condition and problem). The only significant difference involving the State Hint condition was that on the SS decisions in the first problem ($M-h=10.40$ s, $M-nh=7.06$ s, $p < 0.05$).

Discussion

The experimental results provided strong support for the effectiveness of the state hint. This hint promoted the achievement of the criterion in the first problem, while its removal did not produce any performance decrease in the second one. A significant support for the effectiveness of the legal hint was not reached, but the limited power of the tests advises caution in the interpretation.

The results on the percentages of errors clearly showed that the main sources of difficulty for the problem were the Slide-Slide choices. The state hint worked by reducing the errors in these decision points in the first problem, thus allowing a faster development of a decision policy.

However, about 60% of the participants were able to reach the criterion in both the problems, thus demonstrating the possibility to acquire an advantageous solution strategy with a sufficient amount of practice. Furthermore, the performance of the successful solvers in the second problem was quite similar across the experimental conditions.

The error and time results were not compatible with the adoption of the MP strategy. The use of the AB or JRND strategies could not be excluded in the conditions without the state hint, but only in the first problem. The JR and the JS strategies were the only two strategies potentially in accordance with the evidence on the second problem.

The Simulation

We decided to undertake an ACT-R simulation (Anderson & Lebiere, 1998) to formulate more detailed predictions from the partially supported strategies: Avoid Blocks (AB), Jump and Random (JRND), Jump and Retrieve (JR), and Jump and Space (JS), and to test them against the appropriate subset of data. We implemented the four strategies as separate ACT-R models.

While the JRND strategy leads to a direct implementation, the AB and JS require to mentally simulate the execution of the possible legal moves, and to evaluate the states deriving from them. We implemented the construction and storage of the imagined states via time-costly productions, and we assumed that the state evaluations were always performed errorless. Given that verbal protocol data indicated that detecting a block situation is quite an easy task, we assumed also that the AB model did not need to retrieve the simulated move. Conversely, the JS model, being engaged in more difficult distance tests, had to use the error prone memory

retrieval. Thus, the JS model often dictated a move that did not comply with the strategy requirements.

The implementation of the JR strategy required, on the other hand, the memory storage of each Slide-Slide choice, and of the outcome of each trial. When facing a Slide-Slide problem state, the model tries to retrieve the last decision taken in the same situation using the current board configuration as a retrieval cue. It also tries to retrieve the outcome of the last performed trial. If the trial is remembered as a success, the retrieved move will be executed, otherwise the alternative legal move will be carried out. Thus, the JR model sometimes makes the wrong selection due to retrieval errors or to a temporal mismatch between the retrieved move and the trial.

Procedure and Results

We compared the AB and JRND predictions with the data of the first problem without the state hint. Then, we contrasted the JR and JS results with the data of the second problem, in the conditions without the state hint.

For each strategy, we executed a number of simulation runs (2000) sufficient to provide an efficient estimation. The dependent variables were the number of trials to reach the criterion, and the error percentages on the two Slide-Slide choices. The JS-M percentages were not taken into account, because all the strategies predicted few errors in the JS choices and the empirical values are always very close to zero. The experimental data and the simulation results are presented in Table 2 and Table 3 (the number near the strategy label stands for the problem being simulated).

Table 2: Experimental data.

PROBLEM	Trials to Criterion	SS-1 Error	SS-2 Error
FIRST	16.63	43	47
SECOND	9.37	30	35

Table 3: Simulation predictions. (Values within the 95% confidence interval of data are marked with *)

STRATEGY	Trials to Criterion	SS-1 Error	SS-2 Error
AB (1)	13.95*	43*	40*
JRND (1)	13.08	42*	39*
JR (2)	7.56*	34*	37*
JS (2)	13.70	42	39*

The results showed that the AB strategy obtained a slightly better fit than the JRND on the first problem results. The best fit for the performance on the second problem was obtained by the JR strategy. Thus, the most probable explanation is that participants shifted from the AB to the JR strategy as a consequence of their increased experience with the task.

It seems reasonable to assume that the state hint was able to foster the adoption of the JR strategy. A simple memorization of the state hint seems quite implausible, given the move latency data. In the second problem, if the participants were retrieving the state hint and using it to carry out the SS move selection, we should have observed a significant increase in the mean latency. On the contrary, the mean times for the SS moves resulted much lower in the second problem. Furthermore, the whole second problem performance was very similar for the groups with and without the state hint. So, it could be parsimoniously hypothesized that the indirect suggestion of the correct move made available through the state hint could have simply speeded up the natural development of a more general memory-based strategy.

Conclusions

The evidence provided can help us to answer the question that motivated our research on the T&F puzzle. People were able to acquire an effective solution strategy even when hill-climbing or means-ends analysis were not directly applicable. We gained support for a state-avoidance strategy in the initial problem solving attempts, and for a memory-based strategy in later trials. Finally, we demonstrated the effectiveness of a specific type of interface hint.

From a broader prospective, it is worth noting that some findings, obtained in very different settings (Howes & Payne, 2001), seem to bring converging evidence for a kind of memory-based problem solving when weak methods are not applicable or not efficient.

Another meaningful point is that our hybrid memory-based JR strategy was probably derived partly from the weak method of trial-and-error, and partly from the proceduralization of the state-avoidance heuristic. This raises an interesting theoretical issue concerning the ontology of multi-step problem solving strategies. The strategies commonly proposed in the literature seem to belong either to the algorithmic or to the memory-retrieval class. Our work seems to suggest that, in some multi-step situations, people are able to acquire hybrid strategies, relying on memory retrieval to handle problem solving steps where procedural methods don't work. So, in our view, it seems necessary to make a distinction between the strategies that require the intentional usage of memorized instances (Logan, 1988), the ones that keep track of the previous history in a procedural form (Lovett & Anderson, 1996), and the hybrid formulations. This also means that it will be generally necessary to make explicit all the potential candidate solution strategies, and to contrast them in their capacity to fit the data.

Abstract

We compared two automated approaches to teaching *distinguishing*, a skill that involves assessing the relevant differences among cases in a context-sensitive way. We implemented the two approaches in two versions of an Intelligent Tutoring System designed to teach law students basic skills of case-based legal argument. The original version of CATO employs didactic explanation. The newer version, CATO-Dial, teaches the same skill with a simulated dialectic argument in a courtroom setting. We hypothesized that students would learn the skill better by engaging in the simulated argument than by receiving interactive explanation. We expected that dialectic argument would help students to construct the target knowledge on their own as they developed responses to arguments, and that this would lead to more robust learning. We showed that students in the dialectic argument simulation group performed significantly better on a section of the post-test aimed at assessing transfer of their skills of distinguishing. We discuss a number of cognitive and motivational benefits that may explain this effect.

Introduction

The skill of distinguishing is important in dialectical domains such as law, applied ethics, policy analysis, and business, where arguments by analogy are routinely employed in professional education and practice. Distinguishing is a way to respond to an analogical argument. The argument claims that a target problem should be decided in the same way as a cited source case by virtue of their relevant similarities, that is, factual patterns the cases share that form the basis of legal reasons for deciding them in the same way. A *distinction* is a factual difference underlying a legal reason to decide the target problem differently from the cited case. There may be many differences, but only those that give rise to legal reasons for treating the cases differently are distinctions.

A distinction may be a factual strength of a side (i.e., a party, either plaintiff, the one who commences suit, or the defendant) in the target

problem not shared in the source case, or a factual weakness in the source case not shared in the target. For the cases in our experiment, students play the role of the defendant's attorney; a distinction is defined as a pattern of facts that strengthens defendant's legal argument in the problem not found in the cited-case, or a fact pattern that weakens defendant's side in the cited-case not found in the problem.

In order to distinguish effectively, one must be sensitive to the argument context in which a case has been used. The context includes the role a relevant difference plays in an argument, its underlying legal significance both in absolute terms and relative to the other combinations of facts in the target problem and cited precedent.

Professors note that law students often demonstrate only a shallow understanding of the concept of a distinction. Students may be able to find different facts but fail to realize that only some differences are distinctions. Students may also ignore which side a difference favors, or they fail to view the significance of a difference in the context of the other facts in the problem and cited-case. Because of their shallow knowledge, students may make arguments citing differences that hurt, rather than help, their side's argument.

Ideally, students "pick up" the skill of distinguishing through the trial-and-error experience of making arguments. In a law school, students engage in arguments in the classroom. Sometimes, however, students are reluctant to expose themselves in class by making arguments, and, in any event, could benefit from additional instruction outside the classroom. In an effort to meet this need, Aleven and Ashley (1997) developed the CATO program (i.e., Case Argument Tutor), an Intelligent Tutoring System designed to teach basic case-based argument skills, including how to distinguish cases (see also Aleven, 1997).

In designing an ITS to teach distinguishing, one may try two approaches. *Didactic explanation* involves presenting good and bad examples of distinguishing. The system explains

why the examples are instances of successful or unsuccessful argument. The bad examples illustrate the various kinds of shallow knowledge. This is how CATO teaches distinguishing.

Dialectic argument attempts to teach students distinguishing by engaging them in arguments, affording an opportunity to learn the skill through a process of trial-and-error. Technically, it is harder to design this kind of pedagogical interaction. Before undertaking to develop a large-scale dialectic argument system, we wanted to see whether it was likely to improve students' learning. We therefore developed a variation of CATO, called CATO-Dial, which employs dialectic argument to teach distinguishing.

We hypothesized that students would learn better to distinguish by engaging in dialectical argument than in didactic explanation. We speculated that students engaged in role-playing and arguing would encounter information in a more relevant context and would be motivated to process the information more thoroughly. They would develop deeper knowledge of the role a difference plays in the argument context, its interactions with other facts in the target problem and source case and the underlying reasons why it matters. Our experiment tested this hypothesis.

In aiding students to learn deeper knowledge, we also hoped that CATO-Dial would promote better transfer of knowledge. A major problem in knowledge transfer is that people tend to access prior knowledge that bears superficial rather than structural similarity to the problem at hand (Thompson et al., 2000).

Legal argument is not as determinate a form of problem-solving as, say, physics or geometry. Legal problems rarely have provably correct answers; there may be reasonable arguments on both sides of a dispute based on analogies to competing cases (Ashley, 1990). CATO-Dial attempts to engage students in argument dialogues that focus them on comparing cases.

Law school professors engage students in Socratic dialogues about cases in the casebooks. Some of the earliest ITSs used Socratic dialogue and an inquiry teaching method to teach subject matter such as geography (SCHOLAR (Carbonell, 1970)) or meteorology (WHY (Collins and Stevens, 1982)). A subsequent tutoring system (Wong et al., 1997) incorporated the inquiry teaching method into an ITS shell and geography tutor. The OLIA ITS (Retalis et al., 1996) used a related argument dialogue strategy, playing devil's advocate. Research suggests that students tutored manually with Socratic dialogues

learned targeted physics concepts (i.e., rules) better than those taught with more didactic dialogues (Rose et al., 2001). In the latter, the human tutor provided more explanation before asking questions but asked fewer open-ended questions.

CATO vs. CATO-Dial

CATO is one of the few case-based Intelligent Tutoring Systems that teaches a process of case-based reasoning. (Aleven, 1997, pp. 197-8). It provides a set of specialized tools, accessible through an X-server connection to CATO running on a Unix workstation, and a web-accessible Casebook and Workbook. The Casebook presents excerpts from important legal case opinions in trade secret law. A small set of argumentation and discussion questions follows each case, much like an ordinary legal casebook. The Workbook helps students use CATO's tools to analyze and respond to the argumentation and discussion questions.

Experiments show that CATO is an effective teacher (Aleven & Ashley, 1997; Aleven, 1997). Students work with CATO's textual case summaries and abstract representations of cases in terms of *factors*. Each factor represents a stereotypical collection of facts, which tends normally to strengthen or weaken a conclusion that a side should win a particular kind of legal claim (Ashley, 1990). A Factor Hierarchy represents legal reasons why a factor makes a difference to the legal claim (Aleven, 1997).

CATO helps students analyze target problems and compare them to past cases. It teaches novices to identify factors in a target problem, test hypotheses about their significance against cases in its database, and make legal arguments about how to decide the target problems citing cases. Students encounter problems based on real litigated cases. Novice users identify conflicting factors in the problem, which give rise to conflicting reasons for decision. CATO teaches them how to make arguments to resolve such conflicts.

CATO's Argument Maker tool provides a tutorial on distinguishing. To enable CATO to employ dialectic argument, we developed CATO-Dial, a modification of the program that engages novice users in courtroom-style arguments about target problems. In using the CATO-Dial version of the tutorial on distinguishing, students encounter examples like the *Lynchburg Lemonade* case.¹ With the Case Analyzer tool, students have

¹ In the *Lynchburg Lemonade* case, Tony Mason, the plaintiff, developed a cocktail he dubbed "Lynchburg

identified conflicting factors in the *Lemonade* problem and have begun to consider the conflicting factor-based legal reasons about how to decide its outcome. For comparing cases, the Case Analyzer presents them in a tabular form as in Figure 1. The problem has six factors, four of which favor the plaintiff (p) and two of which favor the defendant (d). The *Boeing* case, won by plaintiff (p), shares two of these factors, the relevant similarities (marked with "="). The relevant differences (i.e., distinctions) are the four unshared factors marked with "*". These favor deciding the *Lemonade* case for the defendant (i.e., differently from *Boeing*). Note that F16 strengthens the defendant in the *Lemonade* case and is not found in *Boeing*, whereas F4, F12 and F14 strengthen the plaintiff's position in *Boeing* and are not found in the *Lemonade* case. F10, F15 and F18 are also unshared factors, but they are not distinctions because they favor deciding the *Lemonade* case for plaintiff (i.e., the same as in *Boeing*).

With CATO-Dial, students play the role of an advocate, Perry Mason, who has to argue a case in court. As shown in Figure 2, the student may put arguments in the mouth of Perry Mason by selecting argument moves and values from a menu. CATO-Dial responds on behalf of the Judge, who mediates the proceedings, Hamilton Burger, Perry's opposing counsel, and Della Street, Perry's savvy assistant, who offers helpful hints.

In the dialogue, Mr. Burger's responses (such as step 5 in Figure 2), generated by CATO-Dial, take advantage of any weaknesses in Mr. Mason's argument, based on the students' menu selections. The Judge's reaction emphasizes the student's mistake, and Della's hints, also generated by CATO-Dial, provide instruction on how to correct them. CATO-Dial can engage in dialogues like this for any pair of relevant cases in its database.

Lemonade". Since Tony took some measures to protect his recipe's secrecy, and since he was the only tavern producing this drink, we say factors F6, Security-Measures, and F15, Unique-Product, apply; both tend to favor the plaintiff (p). On the other hand, Tony disclosed his recipe in negotiations with a sales agent of the defendant, Jack Daniel's Distillery. Thus, F1, Disclosure-In-Negotiations, applies, a factor that tends to favor the defendant (d). The agent was aware, however, that the recipe was a "secret formula", so F21, Knew-Info-Confidential, also applies, tending to favor the plaintiff. Without compensating Tony, the defendant started marketing exactly the same kind of cocktail; F18, Identical-Products applies and favors plaintiff. Finally, the recipe could have been obtained by reverse engineering the cocktail; F16, Info-Reverse-Engineerable, applies and favors the defendant.

CATO-Dial's dialectic argument contrasts with CATO's didactic explanation. Originally, CATO's tutorial engaged students in an interactive exercise employing didactic explanation. In these explanations, CATO did not engage the student in as direct a manner. Instead, the student was presented with an argument that a hypothetical opponent could make. Below is an excerpt from CATO's original version of the dialogue of Figure 2. First, CATO makes the same argument as in Step 1 of Figure 2 and invites the student to select the factors that he would emphasize in distinguishing the *Boeing* case on behalf of the defendant. Second, the student again selects three differences (i.e., factors F15, F16, and F18) which though not shared between the two cases, actually strengthen the argument that plaintiff should win in the problem situation. CATO then responds as follows:

3. CATO: Suppose defendant made the following argument: The *Boeing* case is distinguishable, because in the *Lynchburg Lemonade* case, defendant's product was identical to plaintiff's [F18] and plaintiff was the only manufacturer making the product [F15]. This was not so in *Boeing*. Would this really help defendant? When you have answered this question for yourself, please click on "Continue".

4. STUDENTS: (Continue)

5. CATO: Plaintiff could respond to defendant's argument, as follows: Your Honor, as defendant's counsel correctly pointed out, in the current problem, defendant's product was identical to plaintiff's [F18] and plaintiff was the only manufacturer making the product [F15]. *Boeing*, which was won by plaintiff, does not have these strengths on plaintiff's part but is otherwise similar to the problem at hand. Where these additional strengths are present, a decision in favor of plaintiff is warranted even more strongly than it was in *Boeing*. In short, even though factors F18 and F15 are differences, defendant cannot use them to distinguish *Boeing*. Defendant needs to focus on other differences, namely, on those differences that make the *Lynchburg Lemonade* case look stronger for defendant than *Boeing*. Please click on "Continue". See (Aleven, 1997 at 141f).

The argument that CATO uses to show the inadequacy of the student's initial selection of distinctions is the same in both versions; the difference lies in the manner in which it is presented to the students and the way in which students are engaged in the task.

Description of Experiment

We compared the impact of teaching distinguishing to senior undergraduates using the two versions of CATO. The students had all been accepted into law schools and were receiving

preparatory instruction through a summer institute. The students were randomly assigned to two groups. The experimental group used the dialectic argument version of CATO-Dial and initially numbered 22 students. The control group worked with the didactic explanation version of CATO and initially numbered 23 students. Each group worked in a series of eight two-hour sessions over a span of about one month from June 5 through July 11, 2000. For each session a student was paired with a different partner from the same group.

Prior to the series of instructional sessions, all students took a pre-test comprising three questions designed to assess argumentation skills. For Questions 1 and 2, students read a problem situation and three short cases. Students were asked to make and respond to arguments about the problem given the cases. Question 3 asked them to define the concepts of a relevant similarity and relevant difference.

Lynchburg Lemonade Case = F1 Disclosure-In-Negotiations (d) = F6 Security-Measures (p) F15 Unique-Product (p) * F16 Info-Reverse-Engineerable (d) F18 Identical-Products (p) = F21 Knew-Info-Confidential (p)	Boeing (p) = F1 Disclosure-In-Negotiations (d) * F4 Agreed-Not-To-Disclose (p) = F6 Security-Measures (p) F10 Secrets-Disclosed-Outsiders (d) * F12 Outsider-Disclosures-Restricted (p) * F14 Restricted-Materials-Used (p) = F21 Knew-Info-Confidential (p)
= shared factor * distinction	

Figure 1: Case Comparison In Terms of Factors

<p>Court is in session...</p> <p>1. Mr. Burger for Plaintiff (CATO): Your Honor, where plaintiff adopted security measures [F6] and defendant knew that plaintiff's information was confidential [F21], even though plaintiff disclosed its product information in negotiations with defendant [F1], plaintiff should win a claim of trade secrets misappropriation, as in <i>The Boeing Company v. Sierracin Corporation</i>, 108 Wash.2d 38, 738 P.2d 665 (1987).</p> <p>2. Judge (to Defendant's counsel): Your response, Mr. Mason?</p> <p>3. <STUDENT (selecting from menu): Distinguish <i>Boeing</i> [F15] [F16] [F18] (Continue)></p> <p>Mr. Mason for Defendant (Student): <i>The Boeing Company v. Sierracin Corporation</i> is distinguishable, Your Honor, because in the <i>Lynchburg Lemonade</i> case, plaintiff's product information could be learned by reverse-engineering [F16]. This was not so in <i>Boeing</i>. <i>Boeing</i> is also distinguishable, because in the <i>Lynchburg Lemonade</i> case, unlike <i>Boeing</i>, defendant's product was identical to plaintiff's [F18] and plaintiff was the only manufacturer making the product [F15].</p> <p>4. Judge (to Plaintiff's counsel): Mr. Burger?</p> <p>5. Mr. Burger for Plaintiff (CATO): Your Honor, as Mr. Mason concedes, in the current problem, defendant's product was identical to plaintiff's [F18] and plaintiff was the only manufacturer making the product [F15]. <i>Boeing</i>, which was won by plaintiff, does not have these strengths on plaintiff's part but is otherwise similar to the problem at hand. Where these additional strengths are present, a decision in favor of plaintiff is warranted even more strongly than it was in <i>Boeing</i>.</p> <p>6. Judge (to Defendant's counsel): I am sorry, Mr. Mason, but I am afraid I have to agree with Mr. Burger.</p> <p>7. STUDENT: Help! (Continue)></p> <p>8. Della Street (whispering into Perry's ear): Here is a hint. Even though factors F18 and F15 are differences, defendant cannot use them to distinguish <i>Boeing</i>. Defendant needs to focus on other differences, namely, on those differences that make the <i>Lynchburg Lemonade</i> case look stronger for defendant than <i>Boeing</i>.</p> <p>9. <STUDENT (selecting from menu): Distinguish <i>Boeing</i> [F4][F12] [F14] [F16] (Continue)></p> <p>Mr. Mason for Defendant (Student): <i>Boeing</i> is distinguishable, because in <i>Boeing</i>, defendant used materials that were subject to confidentiality restrictions [F14], plaintiff's disclosures to outsiders were subject to confidentiality restrictions [F12], and defendant entered into a nondisclosure agreement with plaintiff [F4]. This was not so in the <i>Lynchburg Lemonade</i> case. Also, in the <i>Lynchburg Lemonade</i> case, plaintiff's product information could be learned by reverse-engineering [F16]. This was not so in <i>Boeing</i>.</p> <p>10. Judge (to Plaintiff's counsel): Mr. Burger?</p> <p>11. Mr. Burger for Plaintiff (CATO): Uhh. Well, as you know, Your Honor, <i>Boeing</i>, is not the only case we cite in our brief.</p> <p>12. Della Street (whispering into Perry's ear): Brilliant job, Perry!</p>

Figure 2: Sample Dialectic Argument in CATO-Dial

During the first six sessions, the experimental and control groups were treated identically. In Sessions 1 to 4, both groups of students familiarized themselves with the factor based representation system and the CATO environment. In Sessions 5 and 6 all students learned how to use the Argument Maker tools.

The control group and experimental group were treated differently in Sessions 7 and 8. These two sessions focused on teaching students how to distinguish cases. During both Sessions 7 and 8, students were expected to complete eight pair-wise case comparisons involving distinguishing. The eight pairs of cases were the same in both groups. The only difference was the manner in which CATO and CATO-Dial taught the lesson. The experimental group worked with CATO-Dial's simulated courtroom dialogues like that in Figure 2. The control group worked with the original CATO didactic explanations.

After Session 8, all students took a post-test comprising six questions. The first three questions were worded identically to the pre-test questions, but Questions 1 and 2 involved a different problem and cases. The other three questions tested the following transfer skills:

- Question 4 put students in a new role – instead of making arguments they critiqued an argument.
- Question 5 tested students' recall of a particular problem situation they had encountered in the instruction. This problem had been used extensively in the teaching sessions as a basis of the argumentation lessons. Students were asked to make and respond to an argument about the problem, which they had to recall from memory, by analogizing it to and distinguishing it from a new case presented with the question.
- Question 6 tested students' ability to apply skills they had learned to an unfamiliar new domain: the copyright law doctrine of Fair Use. As such, this question is a telling measure of their ability to distinguish cases.

The director of the University of Pittsburgh School of Law legal writing program graded all but one of the pre-test and post-test questions. The grader was provided a one-page summary of grading criteria and instructed to assign a gestalt grade (between 1 and 10) to each question. He was blind as to the identity of the test writers, but did know which were pre-tests and which were post-tests. The exception was Question 5, the recall question, for which we developed an objective grading scheme. Students were awarded a maximum of ten possible points on the basis of how many of the factors in the problem they referred to in their argument.

Analysis

Post-test data were available for only 22 of the 45 students, 15 in the experimental group and 7 in the control group. The rest of the subjects either dropped out before the end of the experiment or did not complete enough work in Sessions 7 and 8, the only sessions involving differential treatment of the two groups.

Pre-test scores were analyzed for the 22 students, who provided both pre-test and post-test data. For each student,

responses to the three pre-test questions were summed, and the mean response of students in the experimental group was compared to that of students in the control group, using a two-tailed *t*-test. Results showed no statistically significant difference between the two groups. Since the students were paired with different partners across sessions, we used the individual student rather than the pair as the unit of analysis for both pre-test and post-test analyses.

Post-test scores were also analyzed for the 22 students who provided both pre-test and post-test data. A two-tailed *t*-test indicated no significant difference in the mean post-test scores of the experimental and control groups with respect to the first five questions. For question 6, however, the mean post-test score of the experimental group was significantly higher than that of the control group ($t(7.1) = 3.87, p < .05$, effect size of 1.57).² On question 5, the mean post-test score of the experimental group was nearly statistically significantly higher than that of the control group ($t(20) = 1.39, p = 0.052$, effect size of 0.62). While the difference was not significant the experimental group scored substantially higher on question 4 with an effect size of 0.88.

Figure 3: Comparison of Mean Post-Test Scores

Discussion and Conclusion

Our hypothesis was that students would learn the skill of distinguishing better by engaging in simulated dialectical argument than in interactive didactic explanation. The data confirmed our hypothesis in an interesting way. Whereas dialectic argument was not more effective than didactic explanation in teaching argumentation skills, it was more effective in helping students transfer the skills they learned to new tasks and significantly better in helping students apply the skills to an unfamiliar legal domain. Dialectical argument may have induced students to construct a schema for making and responding to arguments, resulting in deeper knowledge and thus better performance on transfer skills. Experimental students also appeared to have a better understanding of the importance that context plays in the task of finding distinctions. The grader also evaluated the

² Degrees of freedom for this test were reduced from 20 because Levene's test for equality of variances indicated that the variances of scores in the experimental and control groups were not equal.

answers in terms of four grading criteria, each involving a simple binary positive-or-negative scale. Two differences emerged. Students in the experimental group were more often rated positively on the criteria "Avoids making opponent's argument" and "Avoids errors regarding which side strengths favor". These results support the conclusion that the experimental manipulation helped students to learn better when a difference is a distinction.

It is intriguing that the rather superficial transformation from CATO to CATO-Dial in the presentation of the lesson on distinguishing had such a dramatic benefit. After all, both programs presented the same basic information. The critical difference, we believe, is that CATO-Dial's dialectical argument simulation provided that information in a more useful way. The dialectical argument offers several potential benefits, any or all of which may explain the observed difference in transfer scores.

Students may have found the increased level of involvement and the competitive element in the courtroom simulation motivating and thus conducive to paying attention and learning.

Furthermore students may have found it easier to understand the program's responses in CATO-Dial than in CATO. It is awkward for CATO to explain the quality of a student's response by example. The dialectical argument simulation, by contrast, provides a more natural context for illustrating the effect in an ongoing dialogue regarding a student's choices. Students in the experimental group did report finding the dialogues somewhat (though not significantly) more helpful than did those in the control group. When asked, "When CATO did provide instructional feedback, how helpful was it?", the CATO-Dial students rated it as more helpful than did the CATO students ($M_s = 6.76$ and 5.56 out of 10 , respectively).

Role-playing in a courtroom argument, with its cognitive and emotional expectations, may also be important. Courtroom simulation explicitly prompts the student. An interactive style of human tutoring, in which tutors prompted students, supported learning even when tutors did not provide explanations and feedback (Chi et al., 2001). Having been prompted to participate, students may have been more likely to argue the merits to themselves, a task cognitively similar to self-explanation (Chi et al., 1989). Dialectical argument may also induce a student to feel worse about making a mistake than does didactic explanation. If so, students are more likely to pay attention and to care about learning in the former context. Role-playing may also induce students to compare the cases more carefully, helping the transition from shallow to deeper knowledge. In a recent investigation, business school students who compared cases in a study phase were three times more likely to transfer the cases' implicit principle to a new application than were those who simply read the cases for the purposes of advice-giving (Thompson et al. 2000).

The results suggest that the CATO-Dial approach is potentially quite valuable. Since laws change, law

professors value students' ability to transfer skills. Our subsequent work will focus on converting as much of the CATO curriculum as possible to a dialectical format.

Abstract

An initial model of human error in a real-world teamwork environment has been developed. The captain and first officer of a commercial aircraft and the air traffic controllers with whom they interact are modeled as the crew executes an approach and landing followed by taxi operations that take them to their assigned gate. Scenario details and human model development were based on the results of a series of full-task simulation experiments using commercial pilots as subjects. The focus of the experiment was on errors committed by the aircrews during taxi operations. The models developed exhibit the robust behaviors typically exhibited by aircrews and identify psychologically grounded windows for error within that robust behavior.

Human Error Modeling Applied to Taxi Operations

NASA Ames Research Center conducted two full-mission studies of airport taxi operations under low visibility and night conditions. The subject of the studies was the Taxiway Navigation and Situation Awareness (T-NASA) system, aircraft flight deck technology designed to improve commercial airport taxi operations in poor weather while maintaining a high degree of safety (Hooey, Foyle, & Andre, 2000). The T-NASA system includes a head-up display, a head-down electronic moving map display, and directional audio alerts. The studies included a series of baseline trials run without the T-NASA system and a series of trials using various configurations of the T-NASA system. The T-NASA system effectively eliminated very nearly all error, hence the focus of the human error modeling effort was on the baseline trials.

The NASA Ames Advanced Concept Flight Simulator (ACFS) used in the studies provided a generic glass cockpit simulator with a 180-degree field of view and a high fidelity rendering of Chicago O'Hare Airport replicating the airport layout including runways, taxiways, signage, painted markings, lights, concourses, and structures (Hooey & Foyle, 2001). In the first study, 16 two-pilot commercial crews each completed six land and taxi-to-gate trials based on current operations using Jeppesen charts for navigation. Half of the trials were under low visibility conditions with runway visual range (RVR) of 700 feet, and half under night visual meteorological conditions (VMC). In the second study, 18 commercial two-pilot crews each completed three

land and taxi-to-gate trials based on current operating conditions under 1000 foot RVR conditions. In evaluating these studies, Hooey and Foyle (2001) defined navigation errors as taxiing on a portion of the airport surface on which the aircraft had not been cleared and deviating from their cleared centerline by at least 50 feet. Their analysis revealed 26 navigation errors in 150 current-operation trials—errors were committed on 17.3% of the trials.

Modeling Robust Nominal Performance as a Prelude to Modeling Error

As we set out to identify the sources of error (c.f., Deutsch & Pew, 2001) and then to model error in taxi procedures, we started by refining earlier Distributed Operator Model Architecture (D-OMAR) models (Deutsch, 1998; Deutsch & Adams, 1995) that captured the robustness in aircrew procedures. The models represent the multiple task behaviors of each player as the product of a mix of goals and procedures that operate concurrently to proactively address the player's agenda. Expectations integrate anticipated events while anticipated or unanticipated interruptions must be accommodated. Ongoing tasks determine their own execution times and run to completion unless another procedure defined as a competing procedure with greater priority intervenes. A mix of automatic and thoughtful behaviors are modeled without resorting to a central executive responsible for explicitly scheduling all future actions. A thoughtful cognitive act of decision-making is defined as just that, another procedure that determines the action to follow.

The NASA Information to Modelers package included a Nominal Task Sequence (NASA, 2001a) for the T-NASA baseline conditions. This was used as the basis for the development of the approach-and-landing and taxi procedures that the models of the captain, first officers, and air traffic controllers employed. Approach-and-landing is one of the busiest phases of flight, making high demands on the aircrew. In spite of the high demands of getting the aircraft safely on the ground, it is also the time at which the first steps in the subsequent taxi operations are initiated. The crew is in the process of approaching a given runway and already know the concourse and gate toward which they will be heading. Moreover, as specified in the Nominal Task Sequence, at about eleven miles out they discuss with the air traffic controller and among themselves which runway exit

they will take. As we will argue below, the crewmembers each now have in mind one and perhaps several taxi routes they might take to the gate. Once the runway exit information is in hand, the focus of attention returns to landing the aircraft and rollout.

The information provided in the Nominal Task Sequence was also used as the basis for the modeling of the subsequent landing and rollout sequence. As the rollout sequence is completed and the aircraft approaches the designated runway exit, the taxi sequence is initiated. The first officer provides information to the captain on their position relative to the preferred exit based on notes taken when the preferred exit was agreed on. He/she then informs the controller that the aircraft is clearing the runway, both crewmembers then switch their radio frequency, and the first officer contacts the ground controller. At this point, the ground controller provides the crew with the taxi route to the gate and the first officer writes down the taxi route.

It was at this point that we encountered the first instance of a requirement for a coping strategy. Many of the high-speed exits at O'Hare have a very short run to the first intersection and taxiway routings can be unusually lengthy. We encountered this first when modeling a landing on runway 9R using high-speed exit M6 with an immediate left turn onto taxiway M. The first officer was head-down writing out the taxi directives and was late in providing information to the captain on the upcoming immediate turn. At this point, the captain was also listening to the taxi routing and could go with what he/she heard or slow the aircraft and obtain confirmation on the upcoming turn from the first officer. The coping strategy that we modeled had the captain go ahead with the turn as heard and notify the first-officer of the turn as it was executed.

The process for each subsequent turn in the taxi sequence followed the same pattern. As a turn was completed, the first officer would consult his/her routing notes and the airport diagram, and then prompt the captain on the taxiway and direction for the upcoming turn. As expected, the modeled nominal process proved very robust. By simply changing the routing that the ground controller provided, the captain and first officer were able to execute any desired taxi routing. With these robust aircrew processes in place, the challenge was to model taxi sequences that produced errors consistent with those in the baseline T-NASA experiments.

As the captain and first officer meet their responsibilities during taxi operations, the inherent nature of the tasks that they perform provide them each with a different sense of their immediate location and their location with respect to their assigned taxi routing. They each achieve and maintain different levels of local and global situation awareness (Wickens & Preveet, 1995). If they are working well as a team, they will strive to fill each other's gaps in awareness. In building the aircrew models, we felt that it was essential to reflect this level of teamwork.

The captain was modeled as predominantly head-up during taxi operations. He/she announced each turn as it was executed to keep the first officer informed of their immediate location during such periods as the first officer might have been head-down. Meanwhile, the first officer,

working with the airport diagram and written notes on the runway exit and taxiway routing provided the captain with a more global view of their taxiway routing than would have otherwise been available. The teamwork skills of the modeled aircrews were effective in repairing gaps in one another's situation awareness. One effect of providing this level of detail in good crew performance was of course to make the taxiway procedures just that much more robust and error that much less likely.

Making the Wrong Turn at an Intersection

The particular process that produced the errors of interest was the preparation for and execution of the next turn in the taxi sequence as governed by the captain. As modeled, the captain, if left to his/her own resources, must rely on his/her memory of the taxi sequence as conveyed by the ground controller as the aircraft cleared the landing runway. However, the captain gets significant support in this task from the first officer. The first officer takes notes on the taxi sequence as it is received from the ground controller and will, under nominal conditions, prompt the captain with the name of the next taxiway and the direction of the turn required.

Under nominal conditions, the first officer prompts the captain on the upcoming turn and one can reasonably expect that the captain will correctly act in accordance with the prompt. Acting counter to the prompt is an error possibility that we did not pursue. Hence, to find a source for making a turn error at an intersection, we had to construct reasonable scenarios in which the first officer was otherwise occupied and unable to provide the prompt in a timely manner and of course identify an underlying reason for a mistake on the part of the captain. The events that prevented the first officer from providing the prompts are discussed below in the sections providing details on the error scenarios. Here, we examine possible sources for the errors committed by the captain in executing the incorrect turns.

Intention-to-Act

A classical view of the taxiway process might be that, in approaching a turn, the captain has a planning problem whose resolution is then followed by plan execution. Do we in fact need to make a turn at the upcoming intersection and if so, which way? There might be a schema in place for executing the next turn with slots to be filled in for the name of the next taxiway and the direction to turn. In this view of the process, error might come about by incorrectly filling the slot for the next taxiway name, but more probably, the slot for the direction of the turn to make.

We would like to argue in favor of an alternate view in which there are typically several *intentions-to-act* concurrently in process. The intentions may be established at different points in time. One or more of them may lead to a correct turn or to making an error at the intersection. A *winner-take-all* process leads to the execution of one of the intentions-to-act and the correctness of the outcome is the product of the winning intention. At the point of execution, the remaining intentions cease to contend. We label the process intention-to-act to suggest that the process is not the

product of a conscious decision process—it is not a deliberative planning process followed by a plan execution process. There is the immediacy of an automatic, atomic process rather than a sequential process of planning and acting. Each of the intentions-to-act is instantiated with established slot values, rather than with unfilled slot values to be filled by a deliberative process.

Most of the time there is more than one intention-to-act. In the nominal case where the first officer has provided the correct prompt for the turn, the turn is, most likely, simply executed in response to the prompt and most likely in accordance with a pre-existing intention. In lieu of the prompt from the first officer, the captain will act on a pre-existing intention that might lead to the execution of his/her intention to turn or alternatively to pause and query the first officer on the next turn. (We have not pursued the case of the captain's slowing or stopping the aircraft and querying the first officer.) That is, most of the time in the taxi environment, it is reasonable to expect that the captain has an intention-to-act in place and ready to be acted on.

Rather than having a single planning process with slots to be filled from various sources that is followed by a plan execution step, there are multiple intentions-to-act with selection through a non-conscious winner-take-all process. Each of the intentions-to-act has a complete set of immediately filled slots. In the following section, we provide the reasoning supporting this viewpoint.

Intentions-to-Act as Automaticity

At this point, we want to build the case for the idea that in performing relatively simple tasks like correctly executing the next taxiway turn, there may be several competing intentions-to-act. Most may arise as automatic processes that require little or no conscious deliberative thought. They may emerge from different ongoing processes competing in a winner-take-all process to determine the action taken. Occasionally, the winner will determine an action that is in error. During the course of this study, we have attempted to identify some of the sources for these intentions and to provide reasoned explanations on why the errors emerge.

For most of us, there are a broad range of everyday activities that we perform quickly and effortlessly—they appear to be automatic and involve little thought or conscious awareness (Logan, 1988a; James, 1890). Logan (1988a) characterizes this automaticity, the execution of these activities, as fast, effortless, autonomous, stereotypic, and unavailable to conscious awareness. That is, we experience them as fast, effortless, stereotypic, and unavailable to conscious awareness. They are autonomous in the sense that the acquisition of these skills comes about independent of any deliberate intention to learn them.

Logan (1988a) developed the "Instance Theory of Automaticity," a theory for how automatization is constructed. The theory was developed in part through a series of experiments in learning alphabet arithmetic—learning to solve problems of the type "A+2=?" where the answer is "C." Initially, most people solve these problems by explicitly counting out the required steps through the alphabet—they employ an algorithm that they step through

when the problem is presented. Through experience they "learn or remember" the answers.

Logan suggests that *each* learned instance is remembered. When presented with a new problem, there is a concurrent attempt to access a remembered instance of a previous solution *and* an explicit algorithm-based problem-solving computation. The memory access is a comparatively fast process, the algorithm-based process comparatively slow. If the memory access is successful in retrieving a solution, there will be a rapid response to the posed problem. If the memory access is not successful, the response will be slower. Through experience, more and more solutions are acquired and at some point, the deliberative process is simply not a contender in the winner-take-all process. For any given problem, there may be several remembered solutions. Due to the remembering of each solution instance, there may potentially be several correct retrievals. It is the one that is first retrieval that determines the time required to solve the problem.

Logan (1988b) further argues that the memory traces that support automaticity may well support declarative as well as procedural knowledge. Logan (1988b) suggests that we "look more broadly for automatic processes. They need not be restricted to procedural knowledge or perceptual-motor skill but may permeate the most intellectual activities in the application environment." Bargh and Chartrand (1999) further suggest that limits on conscious, intentional control requires that non-conscious processes support much of moment-to-moment psychological life. Here we are suggesting that the captain's procedures for addressing the next turn in the taxiway sequence may sometimes be automatic and that while these will often lead to correct behaviors, they may sometimes lead to errors such as those seen in the baseline T-NASA experiments.

Intentions-to-Act as a Source of Error

Our review of the NASA-provided data on the T-NASA experiments pointed to two important factors that we felt deserved particular attention in our modeling effort. NASA (2001c) identified the importance of the location of the destination gate and its relation to the taxi route. Five errors occurred in 48 instances of required turns *away from* the shortest route to the concourse gate while only seven errors occurred in 534 instances of turns *toward* the concourse gate. At any given intersection, the aircrews had a bias to turn toward their destination concourse gate. When the correct turn was one away from the concourse gate, there was a greater tendency toward making an error.

The second observation was the straightforward one that time pressure can lead to error. There was a greater chance of error when a second turn in the taxi sequence closely followed the previous turn. The time pressure of a second turn closely following a first turn was an important factor in each of the errors that we generated in the modeling effort.

To date, four sources of contending intentions-to-act have been identified and modeled. The first is episodic memory—a source for habit-based actions. Similar situations have been encountered in the past and we have a ready source of responses that have worked well. These are

responses that in the past have proven successful and are generally able to carry us through most of the activities of the day. When they fail this is what Reason (1990) refers to as "strong-but-wrong." In our particular case, the aircrews had a history of previous landings at Chicago O'Hare.

A second source of intention-to-act is context-based expectation, driven by partial knowledge. Explicit partial information provided in the current situation prompts a particular intention. Within the taxi-framework, the captain knows the location of the concourse gate and, based on this knowledge, may reasonably have an expectation that the next turn will take them on the shortest route to the gate. These particular situation-specific information points are sufficient to set up an intention for the next turn.

The third source of intention-to-act is the remembrance of the taxi sequence as provided by the ground controller when the aircraft exited the landing runway. As the aircraft approaches a turn, several minutes may have passed since the ground controller provided the taxi directive. The remembrance may or may not be correct, but it can be the source of an intention-to-act.

The fourth source of intention-to-act in the taxi-framework, and the best-grounded source of intention, is the explicit prompt by the first officer based on written notes on the taxi directives provided by the ground controller. In the nominal case, the first officer's prompt will match the captain's intention and will lead to error free performance.

We modeled the contention between these intentions as a winner-take-all process mediated by priority and explored the impact of varying the priorities of the contending intentions. Within the winner-take-all framework, at the winning intention's transition from intention to action, the remaining intentions cease to contend—within the framework of the model, the procedures that would have implemented those intentions fail. The occurrence and timing of the events that drive the intentions determine how they play out, producing successful behaviors or mistakes that lead to an incorrect turn on the taxiway. In particular, to provide a window for error to occur, it was necessary to set up realistic event chains that prevented the first officer from providing the prompt on the next turn to the captain.

As we have suggested, the team-based nature of the taxi procedures makes them very robust and the challenge has been to create situations in which mistakes will lead to error. This effort focused on two error sequences, each requiring two turns in rapid sequence. For case one, there were two instances of the same error as crews took high-speed exit M7 from runway 9R. At the first intersection after the high-speed exit, each captain turned left toward the concourse gate rather than right away from the gate as directed by the ground controller. In the second case, there were two scenarios that shared a similar turn sequence: after turning onto taxiway F in the first instance and M2 in the second instance, there was a quick right turn onto taxiway B. In each of the scenarios, one of the captains turned left rather than right. The errors were noteworthy, because in committing the error the captains each turned away from their intended concourse gate rather than toward the gate as directed.

Error Driven by Partial Knowledge Our hypothesis is that the incorrect turn following the high-speed exit (see Figure 1) was driven by the captain's expectation that the shortest route to the gate was the route to be taken. (The small arrows that denote the errors in Figure 1 indicate the incorrect left turns taken just after the high-speed runway exit. They are in red when viewed in color—in grayscale, they may be difficult to make out.) The intention-to-act arose at the point of the early discussion of the runway exit with the approach controller and the first officer. At this point, the captain knew the runway exit and the concourse gate, and might reasonably have expected to turn left from the high-speed exit at taxiway M taking him/her toward the gate. It became one intention contending to be executed at the first turn after exiting the active runway. From Reason's (1990) perspective, this is an automatic retrieval process based on similarity-matching and frequency-gambling that opens a window for error.

As the scenario played out in the nominal case, the first officer completed the task of taking notes on the taxiway

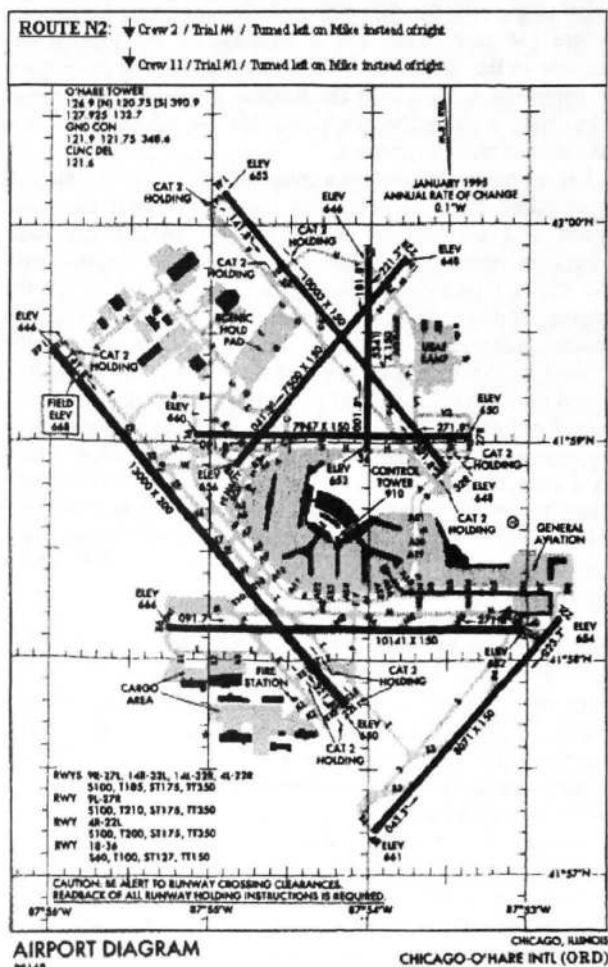

Figure 1: Errors driven by partial knowledge (NASA 2001b).

sequence and then prompted the captain on the first turn following the runway exit. The first officer's prompt triggered a new, contending intention-to-act on the captain's part. The new intention may or may not have been consistent with preexisting contentions. In the nominal case, it dominated and the captain turned right correctly. Given the correct prompt by the first officer, we deemed it highly unlikely that the captain would incorrectly execute the turn.

To open a window for an error to occur, it was necessary to construct a situation that reasonably occupied the first officer, preventing him/her from providing the captain with the explicit prompt on the upcoming turn. The very short run to the first turn after the high-speed exit was the essential factor. The first officer was already busy taking notes on the taxiway routing. Indeed, in some scenarios the taxiway routing was so lengthy that in the nominal case the first officer was still taking notes as the first turn was executed. In this scenario, this was not the case, hence a "mistake" was needed to additionally task the first officer. The failure to preset the radio frequency for the transfer to the ground controller provided the delay. The few seconds necessary to set the new radio frequency provided enough delay to prevent the first officer from prompting the captain before the turn. This was a mistake on the part of the aircrew in the sense that it is always incumbent upon them to complete an action at the earliest available time, rather than risk a situation such as this in which there are contending tasks in process.

Let us recap the captain's intentions-to-act as the aircraft approached the first turn onto taxiway M after the high-speed exit on taxiway M7. The first officer has been otherwise occupied and has not provided the captain with the explicit prompt on the upcoming turn. Based on the coping strategy described earlier, the captain might have a correct intention-to-act based on having attended to the ground controller's taxi directive and an incorrect intention based on the expectation of receiving a shortest route to the concourse gate. Much of the time the coping strategy might be expected to win the winner-take-all competition and lead to a correct turn—some of the time the expectation-based intention-to-act might be acted upon, leading to a taxiway error. Hence, a reasonable, grounded source for an error consistent with the T-NASA experiments has been identified and modeled.

Error Driven by Habit The second scenario examined the surprising cases in which an aircrew incorrectly turned away from the shortest course to the gate (see Figure 2). (In Figure 2, the small arrow denoting the error indicates the incorrect left turn taken just after the short north-bound segments near the center of the airport diagrams. It is in red when viewed in color—in grayscale, it may be difficult to make out.) The basic intention to take the shortest route to the gate would have led to the correct behavior, yet it was not the one acted upon. There were two instances of this error at similar intersections. In the first case (Figure 2), the aircraft was proceeding north on taxiway F and had been instructed to turn right onto taxiway B, but the captain turned left instead. In the second case, the aircraft was

proceeding north on taxiway M2 and had been instructed to turn right onto taxiway B, but the captain turned left. We speculated that a crew whose company gates were on the opposite side of the airport from those required by the scenario might incorrectly turn toward their company gates, exhibiting an error based on long established habit. Requiring an aircrew to proceed to a gate opposite in direction from their company gates might be considered an artifact of the particular scenario, but in a commercial air travel environment that has seen many company failures and mergers, it is not uncommon for aircrews to find themselves working for new companies with new gate locations.

The turn at which the errors occurred closely followed a previous turn, creating a time-pressured situation. Once again, we manipulated the situation such that the first officer was not able to provide a timely prompt to the captain on the upcoming turn. Conflicting taxiway traffic was present on the first officer's side of the aircraft during the approach to the first turn. The first officer informed the captain of the

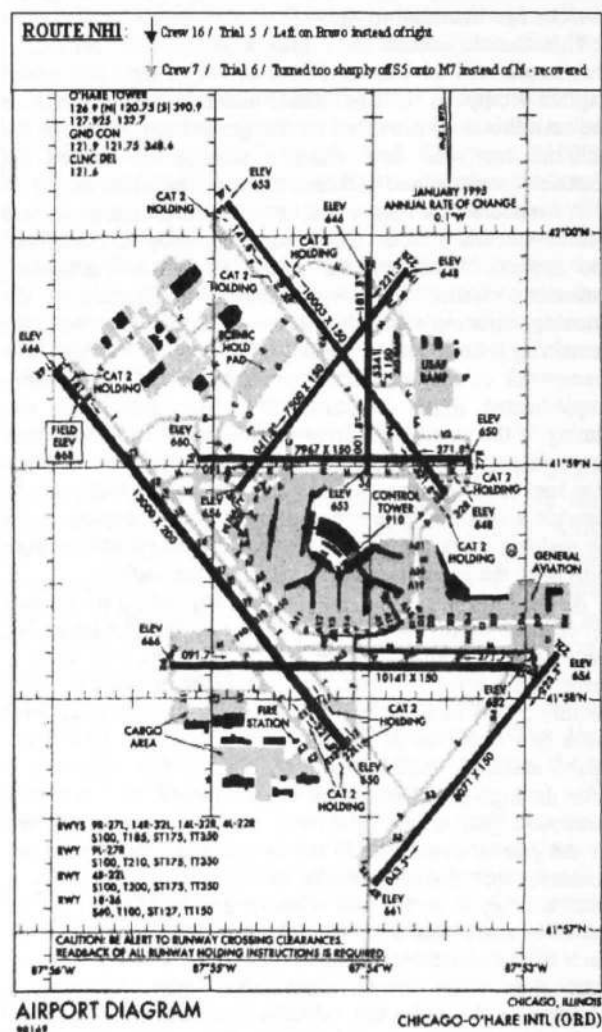

Figure 2: Error driven by habit (NASA, 2001b).

presence of the traffic and continued to monitor the other aircraft. Consequently, the first officer was delayed in going head-down to review his/her notes on the upcoming taxiway turn and checking the airport diagram. Following the delay, the first officer's prompt on the upcoming turn was immediately interrupted by a message from the ground controller directing the other aircraft to hold short of the upcoming intersection, allowing the first aircraft to proceed with the turn. Very slight changes in timing of the interruption would have opened the window for a timely and successful prompt.

In the absence of the prompt, there were still multiple intentions-to-act. As modeled, there were intentions-to-act based on the remembrance of the ground controller's taxi directive and on habit based in episodic memory. When the captain's habit-based intention-to-act won the winner-take-all competition and was acted upon, the error was committed. An informal post hoc analysis of the human subject trial error provided support for the speculation that the model represented (B. Hooy, personal communication).

Heuristically Guided Search of the Error Space

The incidence of error in the current-equipment T-NASA experiments was strikingly high when compared to the typical behaviors of professional aircrews. In general, the low frequency of mistakes and the even lower frequency of mistakes combining to produce errors renders a simple stochastic exploration of the behaviors space impractical. The robustness of aircrew team procedures that employ checking and cross-checking of critical actions means that most mistakes will be caught, further compounding the search task. Estimating error frequency for error types can also be a problem. The frequency of some errors (e.g., discrimination of taxiway signage) might be reasonably estimated; the frequency of others (e.g., the onset of a particular intention-to-act) is more difficult.

Timing is also critical. Very small variations in timing can open or close the window in which an error might occur. Timing was particularly critical in the scenario in which the habit-based error occurred. The combination of the demand on the part of the first officer for head-up time to monitor the approaching traffic and the precise moment of the ground controller's interruption of the first officer's prompt for the upcoming turn was necessary to open the window to error. It might well have been possible to generate many hundreds of runs, slightly varying several of the timings, and never have produced a single habit-based error.

To address this problem, we have employed a heuristically guided search of the space in which forced sequences of mistakes are generated, looking for those that lead to error. The errors produced to date are initial examples of the product of such a process. We have identified several novel potential sources of mistakes and worked to create situations in which they might reasonably be expected to occur. We have taken advantage of the time pressure inherent in the closely spaced turn sequences to manipulate the timing of events to construct sequences of

mistakes that do in fact lead to error. For the present, this heuristically guided exploration of the error space has been manipulated by hand. In the future, we would like to move toward a more automated exploration of the error space.

Abstract

In this study, we describe the influences of qualitative changes to the reasoning problem on the reasoning process. The first manipulation is the quality of the test context: A rule is learned in a certain context and contradicted in another. The belief in the rule is then measured in the learning context, the contradictory context, and a new context. The second manipulation is the quality of contradiction: The contradictory rule can neutralize or inverse the learned rule. Both qualitative changes influence the belief revision process.

Introduction

Research in Artificial Intelligence is often conducted to develop systems that think/act rationally (or like humans, depending on the approach). Minsky (1975) was one of the first to point out the problem with deductive systems, and from then on, several researchers developed non-monotonic reasoning systems (for an overview, see Brewka, Dix, & Konolidge, 1997).

While these systems can be very interesting from the viewpoint of an engineer, Rips (1994) mentions two main reasons why these nonmonotonic logics are less than ideal for cognitive purposes: They do not lend themselves to simple implementations (higher order logics are incomplete) and they do not seem to reflect the deliberations that actually underlie human reasoning with defaults. He (1994, p. 299) stated: "For purposes of philosophy (and perhaps AI), we need normative rules about how to change our minds in the face of conflicting evidence; for purposes of psychology, we also need descriptive information on how people deal with the same sort of conflict."

Elio and Pelletier (1997) wrote a pioneering article on this topic. In their experiments, they first presented participants with a conditional premise and a categorical premise that affirmed the antecedent [or denied the consequent]. Then, they added a third piece of information, which conflicted with the conditional

and the categorical premise. This piece of information was a categorical premise denying the consequent [or affirming the antecedent]. The three pieces of information together are in contradiction with the valid Modus Ponens [Modus Tollens] argument: If A then B, A, thus B [If A then B, not-B thus not-A].

Participants were asked to resolve the contradiction by rejecting one of the two first pieces of information. Elio and Pelletier (1997) observed that participants chose to disbelieve the conditional premise rather than the categorical one when resolving the contradiction.

Their results were refined by Dieussaert, Schaeken, De Neys, and d'Ydewalle (2000) and by Politzer and Carles (2001). They found that the initial belief in the conditional premise influenced the belief revision choice that participants prefer to make. When participants had a strong belief in the conditional premise, the preferred to reject (doubt) the categorical premise, when the conflicting information is added. When participants had a weak belief in the conditional premise, the results of Elio and Pelletier (1997) were confirmed: In this case, participants prefer to reject (doubt) the conditional premise.

This shows that it is important in belief revision research to be aware of the belief state participants hold before conflicting information is presented. Therefore, we conducted a measure of the initial belief state in the following experiments, before adding conflicting information.

The following experiments were inspired by research in the field of conditioning. Among others, Bouton (e.g., 1988, 1994) showed that the extinction of behavior does not necessarily means the rejection of a learned rule. One of the phenomena that confirm this hypothesis is 'renewal': When a behavior is learned in context A, and extinguished in context B, the behavior might show up again with a new test in context A. Bouton explains this phenomenon as follows: Individuals learn a dominant rule and exceptions to this rule in certain contexts (see also: Holyoak, Koh, &

Nisbett, 1989). As a consequence, a stimulus that has lost his value as a reinforcer, becomes an ambiguous stimulus from which the specific value is determined by the context. In other words, Bouton points to the importance of the presence of a certain context as an indicator of the belief in the (conditional) rule when an individual is confronted with conflicting information to that rule. In the forthcoming experiments, we will also work with context embedded situations, to gain more insight in the relative value of the contra-evidence.

Another uniqueness of the present experiments is that the participants' belief state is measured by the behavior they pose, and not by what they say their belief is. We think it is as important to know how individuals act on their beliefs, as it is to know how they describe their beliefs. Moreover, De Neys, Dieussaert, Schaeken, and d'Ydewalle (2000) found a strong correspondence between what participants say about their beliefs and how they actually act upon these beliefs, in experiments comparable with the ones presented below.

Briefly, on a technical level, the following experiments are designed as follows: first, the initial belief in a rule is tested. Then, contradictory evidence is presented in a different context, and finally, the belief in the rule is again evaluated by examining participants' manifested behaviours. On the content level, the experiments describe the influence of qualitative changes to the reasoning problem on the belief revision process.

Experiment 1: Pilot study

In this part, we describe a study that tests whether formerly used instantiations of the quality of contra-evidence were well chosen.

Before that, we explain the two hypotheses that are at issue in this manuscript and we depict the important role that the pilot study has regarding the second hypothesis. Subsequently, we give a brief overview of the content of the experiments.

Two hypotheses are evaluated in this manuscript. The main hypothesis is that when a conditional rule is acquired in a first context (A) and contradicted in a second context (B), the belief in the conditional is not affected by the contradictory information when tested in the first context (A) or in a new context (C). Indeed, if the rule acquired in the first context really is a dominant rule, and if the conflicting information learned in a second context is perceived as exceptional, one should also apply the dominant rule in a new context.

A second hypothesis is that the quality of the contradictory information plays a role in the belief revision process. Bouton (1988) focused on the *extinction* of learned rules. With extinction, a learned rule is often only neutralized (e.g. food – no food). Our

hypothesis is that when the conflicting information has a stronger impact (compare with: food – shock), this may affect the belief revision process in a different way. More precisely, we hypothesize that when the contradictory information merely neutralizes the acquired conditional rule, its effect on the belief revision process is smaller than when it reverses the acquired conditional rule. Or, in other words, we suppose that when the acquired rule is reversed, this might affect the final belief state tested in context A and C anyway, despite the fact of a buffering context element (B) when the contradictory information is provided.

It is made very clear in the fore mentioned examples that the absence of an appetitive stimulus (neutralizing) is not the same as the presence of an aversive stimulus (reversing). An adequate test of the second hypothesis is only possible if both stimuli are well chosen.

In a former series of experiments (Dieussaert, Schaeken, & d'Ydewalle, 2002), the manipulation of the quality of the contra-evidence did not result in significant differences, contrary to our second hypothesis. Before drawing any theoretical consequences from this finding, we examine whether those instantiations were appropriately chosen. The pilot study (Experiment 1) was set up to test this hypothesis.

To convey a good understanding of this pilot study and its consequences possible, we briefly describe the content of the former experiments (Dieussaert et al., 2002). The motivation behind the experiment is related to that behind the conditioning experiments of Pineño, Ortega, and Matute (2000). Participants are in a war area, leading a rescue mission. They are told they should rescue as many refugees as possible from a building and they can do this by loading the refugees on a truck. Importantly, they should only fill the truck with refugees if the road is free of mines. They can learn whether the road is safe because coloured lights indicate it. Therefore, they should learn as fast as possible the meaning of these lights.

The participants learn the meaning of the lights in a first location (context), and then move to a second location where they learn that the meaning of some lights is reversed or neutralized. For example, a green light in the first location might indicate that the road is safe, while in the second location it indicates that the road is mined (reversal) or that no information about the road is available (neutralizing). Finally, they move to a third location. At this location, identical or different from one of the former contexts, the participants' belief regarding the meaning of the lights is examined.

In this pilot study (Experiment 1), we manipulate the feedback that participants received in the test phase. Three forms of feedback were distinguished: clearly

positive feedback, clearly negative feedback, and the feedback 'no information available'. The hypothesis is that participants interpret the latter feedback as negative.

Method

Participants. The 36 participants are candidate students at the University of Leuven, Department of Psychology and they participated as a partial fulfillment of a course requirement. Each student was randomly attributed to one of two groups (12 per group).

Design One variable was manipulated between subjects: Feedback. The three levels of this variable were manipulated in the test phase.

The dependent variable is the number of times participants press on the space bar during a fixed time interval when the cue light appears. The meaning of a space bar press is that a person is put in the truck. Each press is thus equivalent to the saving of one person. This dependent variable is measured in the three phases of the experiment: the confirmation phase (9 blocks), the contradiction phase (9 blocks) and the test phase (4 blocks). This behavioral measure is taken as a measure of belief state. The idea behind it is that the more the participant believes that the road is free of mines, the more persons (s)he will put in the truck.

Each block consists of four trials. A trial lasts four seconds. During these four seconds, a colored light is shown (green, blue, red or white). The sequence of the lights is randomized within each block. Participants learn the meaning of these lights (see below) by pressing the spacebar. One of these lights is the cue light, one is the neutral light and the other two do not have a fixed meaning. Each light's meaning is counterbalanced between participants.

The first eight blocks are considered as learning blocks; they are not included in the analysis. All participants acquired a constant pressing level for the cue light within these blocks. The cue light indicates a safe road. The neutral light indicates that the road is closed. The meaning of the other lights differs randomly over blocks; they can indicate that the road is mined, safe, or closed. The context is a location, which we refer to as context A.

The confirmation phase consists of nine blocks. The meaning of the lights is equal as in the learning blocks. The context does not change either.

The contradiction phase consists of nine blocks. Here, the cue light indicates a mined road. The neutral light indicates that the road is closed. The meaning of the other lights differs randomly over blocks; they can indicate that the road is mined, safe or closed. The context is a location, which we refer to as context B.

The test phase consists of four blocks. The test phase always takes place in the same context as the confirmation phase (A), but the feedback varies between groups. For the ABA/+ group, the message 'n

persons saved' is displayed after the cue light lit up in the test phase, while for the ABA/- group and the ABA group, the messages are 'n persons died' and 'no information available', respectively. The neutral light indicates that the road is closed. The meaning of the other lights differs randomly over blocks; they can indicate that the road is mined, safe, or closed.

Procedure The experiment was carried out individually, on computer. All participants received the same instructions. They were told to imagine that they were in charge of a rescue mission. Refugees were hiding in a building that could be attacked by the enemy. Furthermore, these people can only be rescued safely, by placing them in a truck, if the road is free of mines. People are loaded in the truck by pressing the spacebar. To know whether the road is safe, the participants have to learn the meaning of the lights that appear on each trial. Some of the four lights have a fixed meaning (road safe, road mined, road closed); other lights are distracters and have no fixed meaning. The feedback they receive is 'n persons saved', 'n persons died', or 'road closed'.

Moreover, sometimes no information is available about the situation of the road, so that the participants do not know whether the persons they placed in the truck were saved. It was stressed that they should only press the spacebar continuously in case they were very sure that the people would be saved in that trial.

Finally, they were told that different rescue missions could take place and that a beep sound signaled the start of a new mission. The importance of keeping in mind the location (context) where the rescue mission took place was stressed. They were told that the lights could have different meanings in different locations.

Results

Table 1 shows the mean number of space bar presses, (i.e., persons put in the truck) within a fixed time interval. Neither in the confirmation phase, nor in the contradiction phase, did we observe any differences between the groups.

Table 1: Mean number of presses per phase per group.

	CONFIRMATION PHASE	CONTRADICTION PHASE	TEST PHASE
ABA/-/	34.9	7.1	14.9
ABA	45.5	2.5	27.5
ABA/+	42.6	4.9	39.1

An ANOVA shows a main effect of Feedback ($F(2,33) = 7.80, p < .005$). The ABA group scores higher in the test phase than the ABA/- group ($F(1,33) = 4.20, p < .05$), but does not differ from the ABA/+ group. The latter group differs strongly from the ABA/- group ($F(1,33) = 15.58, p < .0005$).

A more detailed planned comparison analysis on the four blocks of the test phase moderates the picture. The three groups do not differ from each other in the first block. The ABA group differs significantly from the ABA/- group in the second block (36.7 vs. 9.4; $F(1,33) = 14.24$, $p < .001$), but differs significantly from the ABA/+ group in the third and fourth block of the test phase (17.8 vs. 42; $F(1,33) = 10.54$, $p < .005$ and 18.7 vs. 36.3; $F(1,33) = 5.51$, $p < .05$, respectively). For these last two blocks, no difference with the ABA/- group could be observed.

Discussion

The feedback message 'no information available' does not function well as a neutralizer of a conditional rule. The message is not interpreted as the absence of an appetitive stimulus, but rather as the presence of an aversive stimulus. Indeed, after a few trials the effect of this feedback message does not differ from other negative feedback, such as the message 'n persons died'.

Experiment 2

Now that we have shown that the message 'no information available' is interpreted as negative rather than as neutral feedback, we have good reasons to believe that it was not appropriate to use this message as an instantiation of the neutralizing level as was done in former experiments (see: Dieussaert et al., 2002).

In the present experiment (Experiment 2), we test the two hypotheses at issue, and focus on the more appropriate qualitative manipulations of the contradiction evidence. Our main hypothesis is that a conditional rule acquired in a first context functions as a dominant rule. Conflicting information learned in a second context is perceived as exceptional. Therefore, one should also apply the dominant rule in a new context.

Our second hypothesis is that the quality of the contradictory information plays a role in the belief revision process. More precisely, we suppose that when the acquired rule is reversed by contradictory evidence, this might nonetheless affect the final belief state in both context A and context C, despite the existence of the buffering context element (B).

Method

Participants Seventy candidate students at the University of Leuven, Department of Psychology, participated in this experiment. They did not participate in the former experiment and participated as a partial fulfillment of a course requirement. Each student was randomly assigned to one of six groups (11 in the ABB- and ABC-Weak group; 12 in the other groups).

Design The independent variables, Test Context and Contradiction Level, were manipulated between

subjects. We distinguish three instances of the variable Test Context: The context in the test phase can be the same as the context in the confirmation phase (ABA), it can be the same as the context in the contradiction phase (ABB) or it can differ from both (ABC).

The second independent variable, Contradiction Level, consists of two instances: The contradiction can be Strong, when the meaning of the rule is reversed, or can be Weak, when the meaning of the rule is neutralized.

The dependent variable is the same as in Experiment 1: The number of times participants press on the space bar during a fixed time interval when the cue light appears. Again, this variable is measured in the three phases of the experiment: the confirmation phase (9 blocks), the contradiction phase (9 blocks) and the test phase (4 blocks). This behavioral measure is taken as a measure of belief state.

Each block consists of four trials. A trial lasts four seconds. During these four seconds, a colored light is shown (green, blue, red, or white). The sequence of the lights is randomized within each block. Participants learn the meaning of these lights (see below) by pressing the spacebar. One of these lights is the cue light, one is the neutral light and the other two do not have a fixed meaning. Each lights' meaning is counterbalanced over the participants.

The first eight blocks are considered as learning blocks; they are not included in the analysis. All participants acquired a constant pressing level for the cue light within these blocks. The cue light indicates a safe road. The neutral light indicates that the road is closed. The meaning of the other lights differs randomly over blocks; they can indicate that the road is mined, save, or closed. The context is a location, which we refer to as context A.

The confirmation phase consists of nine blocks. The meaning of the lights is equal as in the learning blocks. The context does not change either.

The contradiction phase consists of nine blocks. Here, the cue light indicates a mined road in the Strong contradiction level. In the Weak contradiction level, the message 'road closed' is displayed with a cue light. The neutral light indicates that the road is closed. The meaning of the other lights differs randomly over blocks; they can indicate that the road is mined, save or closed. The context is a location, which we refer to as context B.

The test phase consists of four blocks. In this phase, simultaneously with the cue light, the message 'no information is available' is displayed. The neutral light indicates that the road is closed. The meaning of the other lights differs randomly over blocks; they can indicate that the road is mined, save, or closed. The context varies over groups: It can be the same as in the confirmation phase (A), the same as in the contradiction phase (B) or different from those two (C).

Procedure See Pilot study (Experiment 1)

Results

No differences between the groups could be observed in the confirmation phase. This was expected since at that moment no manipulation was introduced yet. In the contradiction phase, the Strong groups scored lower than the Weak groups, as we hypothesized (2.4 vs. 7.6; $F(1,64) = 7.6, p < .01$). Within the same level of contradiction, no differences were observed. Table 2 shows the means for each group.

Table 2: Mean number of presses per phase per group.

		CONFIRMATION PHASE	CONTRADICTION PHASE	TEST PHASE
ABA	Strong	45.5	2.5	27.5
ABB	Strong	41.2	1.8	2.1
ABC	Strong	41.0	2.8	2.5
ABA	Weak	44.0	10.9	40.4
ABB	Weak	44.0	8.3	7.3
ABC	Weak	46.2	3.6	2.9

An ANOVA shows a main effect of Test Context ($F(2,64)=73.21; p<.00001$). The score of participants from the ABA group (33.9) is higher than the score of participants from the ABC group (2.69; $F(1,64) = 118.36, p<.00001$) and the ABB group (4.70; $F(1,64) = 98.65, p<.00001$).

The manipulation of Contradiction Level resulted in a main difference between both levels (10.69 vs. 16.87 for the Strong and Weak contradictions respectively; $F(1,64) = 6.71, p<.05$) in the expected direction. Neither the ABB group, nor the ABC group has a different score in the Strong and Weak group. The main effect results from the difference in the ABA Strong and Weak group ($F(1,64) = 10.05, p<.005$).

The ABA Weak score in the test phase does not differ from its score in the confirmation phase, while the ABA Strong score does ($F(1,64) = 19.79, p<.00005$).

Discussion

The effect of Contradiction Level is now adequately obtained due to an appropriate choice of the instantiation of the Weak level. Only the groups where learning and test context are the same, are affected by the Contradiction Level manipulation: When the contradiction merely neutralizes (i.e., does not reverse) a previously learned rule, no belief revision takes place. When the contradiction is strong, the belief in the rule decreases compared to the learning phase. This observation is surprising given that the contradiction takes place in another context, and could therefore be easily neglected.

On a theoretical level, it would be tempting to conclude that the rule acquired in context A can be considered as a dominant rule. One could state that the

first and the second hypothesis are thus confirmed: The belief is not influenced by the contradictory information in context B, when this conflicting information neutralizes the learned information, but it is influenced when the conflicting information reverses the learned information.

However, this conclusion would be false because for each Contradiction level, the belief in the rule remains low when it is tested in a new context (C). If the 'dominant rule' hypothesis were correct, the belief in the new context should be as high as in the confirmation phase, at least for the Weak level group.

General Discussion

We manipulated two qualitative factors, Test Context and Contradiction Level, to test their influence on the belief revision process. Regarding Test Context, we hypothesize that when a conditional rule is acquired in a first context (A) and contradicted in a second context (B), the belief in the conditional is not affected by the contradictory information when subsequently tested in the first context (A) or in a new context (C).

This hypothesis was inspired by Bouton (1988, 1994), who stated that an acquired rule is protected against extinction when the conflicting information is presented in another context than the learning context, because individuals interpret the first rule as the dominant rule and other one as the exception.

Regarding Contradiction level, the hypothesis was that the quality of the contradictory information plays a role in the belief revision process. We supposed that when the acquired rule is reversed, this might affect the final belief state tested in context A and C anyway, despite the buffering context (B) of the contradictory information.

The influence of the variable Test Context is clear: Given the same learning (and confirmation) and test context, less belief revision takes place after contradictory information is presented in a different context, than when learning and test contexts differ.

The influence of the variable Contradiction Level is also clear. Given an appropriate choice of the absence of an appetitive stimulus (road closed) and of the presence of an aversive stimulus (road mined), the manipulation resulted in a significant difference between the Weak and the Strong level. This effect was mainly due to the effect in the ABA group. For this group, no belief revision took place when the contradiction neutralized the learned rule, but belief revision was observed when the contradiction inversed the learned rule.

Although this effect on the ABA group confirms both hypotheses, one should not be too optimistic about the theoretical consequences because no such effect was

found for the ABC group, which plays an important role as a control group.

Therefore, the results may put serious question marks on the theoretical translation into 'dominant' and 'exception' rules. The results of these experiments may indicate that different rules are learned within each context.

However, from an economical viewpoint on the learning process, this idea does not seem very fruitful. Learning and applying conditional rules would become a very heavy task if every new context implied a new rule.

An interesting distinction, that was not made thus far, could be between conditional rules that are learned (and mostly applied) in one restricted context and conditional rules that are learned (and applied) in a wide range of different contexts.

Our experiments investigated the former situation. It might be that in the latter situation rules that are applicable in more contexts may become dominant rules and rules that are only applicable in one or a few contexts may become exceptional rules. Surely, this idea needs supplementary testing.

In sum, the results of these experiments indicate that the belief revision process is influenced by various qualitative characteristics of the problems. More precisely, this study shows the effect of contradictory context and the level of contradiction. Although the theoretical consequences of these results are not clear for the time being, some handouts for further testing are provided.

Sharing the considerations of Rips (1994) regarding human reasoning, we conclude with an amendment to his statement: For purposes of psychology, we need more descriptive information and theoretical explanations on how people deal with conflicting information.

Acknowledgments

This study was carried out with support from the IUAP/PAI P4 and from the Fund for Scientific Research Flanders Project G.0239.02.

We wish to thank the reviewers and Uri Hasson for their helpful comments.

Abstract

Analogies produced in twenty-five US eighth-grade mathematics classroom lessons were analyzed according to their frequency and structure. Frequency findings suggest that analogies are a common part of mathematics classroom learning, and a component analysis revealed regular structural patterns in the way these analogies are produced. Teachers tended to organize the analogies by producing the target, source, and mapping steps before students become active participants. Students were most likely to then make inferences, adapt them to the target context, and solve target problems. Student participation was either independent or co-constructed with a teacher or other students. Findings address an important correlate with experimental research on analogical reasoning.

The United States' educational system is presently struggling to find teaching programs that facilitate mathematical understanding that goes beyond algorithmic knowledge. Standardized test results recently released in California indicate that despite improvements, the educational system remains far below state goals in mathematics (STAR, 2001). One major component of this difficulty is a lack of knowledge about how to teach abstract concepts so that students are able to transfer this learning across contexts.

Systematic use of analogy may be integral to a teaching program that meets that goal. Analogy is a comparative structure that highlights abstract structural relations (Gentner, 1983), and facilitates schema acquisition and transfer across problems (Gick & Holyoak, 1983). Learning mathematics requires development of generalized concept representations that can be applied across contexts (Bransford, Brown & Cocking, 1999).

Cognitive scientists have argued for decades that analogy plays a central role in human cognition, learning and problem solving (e.g., Holyoak, Gentner & Kokinov, 2001; Kolodner, 1997; Holyoak & Thagard, 1995; Gentner & Toupin, 1986; Piaget, 1950). However, there have been paradoxical findings in analogy research. While analogy has been demonstrated to be used in several everyday

contexts (e.g. Dunbar 1995, 2001), most laboratory studies show low rates of spontaneous noticing and use of analogies for problem solving (e.g. Gick & Holyoak, 1980, 1983). It is necessary to understand this discrepancy between observed patterns of analogical reasoning in the laboratory and in everyday contexts, termed the analogical paradox (Dunbar, 2001), in order to design meaningful interventions to promote educational usage of analogy.

We suggest that in order to clarify the paradoxical findings concerning analogy use, detailed analysis of everyday analogy usage is essential, because important aspects of analogy use can only be understood through online analysis of the pragmatics governing analogy production. The current study uses discourse analytic techniques to explore analogy production in the context of teaching mathematics in eighth-grade mathematics classrooms.

Methods

Sample and Coding

Twenty-five videotaped eighth-grade mathematics lessons were analyzed to examine analogy activities. The lessons were randomly selected from a larger random probability sample collected as part of the Third International Mathematics and Science Study (TIMSS) directed by Jim Stigler (see Stigler, Gonzales, Kawanaka, Knoll, & Serrano, 1998). All selected classrooms were videotaped on one occasion. The classrooms were selected from US public, private, and parochial? schools in both urban and rural areas, and videotaping was conducted throughout the school year. The lesson content was not constrained, but most lessons drew from number theory, geometry, or algebra domains. Teaching styles similarly were not constrained and thus reflected a range of techniques and perspectives.

Lessons were analyzed using V-Prism, a computer software package designed to allow simultaneous viewing of a digitized video and its typed transcript on a computer screen. In the program, the video's transcript is time-linked so that the lines of text move temporally with the video.

The transcript may be marked with codes to designate when an episode begins and ends.

Six levels of analysis were developed such that every lesson was coded in six passes. Each pass was conducted by at least two coders and intercoder reliability was assessed. Codes and frequency data are presented below.

1. Identifying analogies

The definition of analogy used in this study was based on Gentner's structure mapping model (1983). Analogy was operationalized as a comparative structure between familiar objects, termed the *source* (or *base*) of the analogy, and relatively unfamiliar objects, termed the *target* of the analogy. *Objects* were defined as entities that function as wholes at a given level of analysis. The source and target objects are aligned according to their *predicate*, or relational, structure such that inferences are drawn from the source predicate structure to explain the target predicate structure. *Mapping* is defined as the process of aligning and drawing inferences between the source and target objects. Inferences are then drawn from the source structure and used to derive novel knowledge about the parallel target structure. Several constraints govern which mappings are made in each analogy, since all possible mappings are not typically completed (see Holyoak & Thagard, 1989).

Coders used a conservative measure of analogy, marking only units where a source, a target, and clear structural mapping between the source and target could be identified in discourse or explicit gestures. Two examples illustrate typical analogies. Reliability between the two coders was calculated on 105 protocols in 4 lessons (18% percent of the total sample). Agreement was 86%. Differences were resolved in discussion and consensus between the coders.

Figure 1 provides an illustration of the type of analogy typically identified in the data. This is a transcript of an analogy presented by a teacher to a whole class. The teacher is standing at the board, where the formula for circumference and a drawing of a circle is projected behind him.

Construction of Source object:	Teacher: Now here's how I always looked at it. We're gonna say this- this circle right here is an orange
Highlighting the predicate structure:	Its an orange
External layer of (peel, orange)	Alright? Its an orange Now lets say we're gonna take - stick a needle in the orange n' suck out everything inside except for the peeling of the orange. ((demonstrates gesturally)).
Mapping: orange peel to circumference	Okay we're gonna pretend like that's our

	circumference right there.
Adapting the inference (this object will be an external layer) to the context of a geometric circle	((teacher uses a pointer to run along the outside edge of the circle on the overhead projector))

Figure 1: Example Analogy

A total of 103 analogies were identified as verbally produced by classroom participants. Lesson included a mean of 4.1 analogies ($SD = 2.6$). The range for individual lessons was between 1 and 11 analogies. Thus in every lesson examined, at least one explicit analogy unit was coded.

2. Participant Organization.

Each analogy unit was examined to record the roles played by teachers and students. Based on empirical and computational models of analogy, coders specifically determined whether a teacher, a student, a group of students, or no one generated the four steps of analogical reasoning demonstrated above in figure 1 (source, target, mapping, inference and adaptation, and problem solving).

Findings revealed that most analogies were initiated by teachers, and those produced by students tended to be highly superficial and only occurred in two classrooms (3% of the total number of analogies coded). Teachers produced 84% of sources, 77% of targets, and 89% of mappings. Students had a comparatively more active role in developing inferences and adapting them to target contexts, produced 27% alone or collaboratively with the teacher. Finally, students were most active in completing computations to provide final answers to target problems. Although only 42% of analogies had an explicit answer, students supplied 38% of those answers.

3. Source Structure

In order to examine the types of sources and targets produced typically in these mathematics analogies, the structure of the source and the target were independently coded for each analogy unit. Five classification categories were used. There were: 1) decontextualized math problem, 2) contextualized math problem (i.e., a word problem set in a non-math context), 3) schema (general rule, no surface features), and 4) outside math phenomena. If more than one source was used to explain the same target, or the target was stated in two ways, the source was coded "multiple." See Figure 2 for sample analogies of each structure.

Intercoder reliability was calculated separately for coding source and target. 22 protocols were used from 3 lessons (approximately 15% of the analogies coded). Reliability was calculated to control for chance using Cohen's Kappa, yielding $k=.72$ and $k=.81$ for source and target reliability (acceptable to good levels).

Both the sources and targets displayed significant differences between the frequency with which each structure

category was used, $\chi^2(4) = 26.5; 68.4; p < .001$ in both cases. While both sources and targets were most likely to be decontextualized math problems (40% and 44%), all four categories were represented. The next largest proportion of targets were math schemas (33%), suggesting that teachers were using analogies not only to prompt solutions to single problems, but also to aid in developing more general schemas. The most substantial distinction occurred between objects outside the domain of mathematics used as sources and targets. 15% of sources were outside the domain of mathematics, while only 1 out of 103 targets was a non-math phenomenon. This is not entirely unexpected since the math classroom is oriented towards mathematics learning, but it is conceivable that mathematics classrooms would discuss how to apply math structures to understand real-world problems. Finally, there were more multiple sources used (16%) than multiple versions of the target (5%).

Table 1: Structural composition of analogy sources and targets

STRUCTURE	FREQUENCY	
	Source	Target
Not math	15	1
Contextualized	19	18
Decontextualized	41	45
Schema	12	34
Multiple	16	5
Total	103	103

The overall level of similarity between the surface features of the source and the target was coded on a four point scale, as suggested by research indicating that this relationship governs the reasoning used to solve an analogy (e.g. Ross, 1987; Gick & Holyoak, 1983).

	Source	Target	Surface Similarity
1	Outside-math phenomena: <i>It's like balancing a scale, matter doesn't disappear, so to keep it balanced, whatever we do to undo one side we have to do to the other.</i>	Decontextualized math problem: <i>It is divided by negative sixty, so we multiply by negative sixty on both sides.</i>	Far distance
2	Contextualized math problem: <i>Lets say you've got money. If you lost 88 cents and then you lost 5 cents more, would you add or subtract to find out the total amount you lost?</i>	Math schema <i>When you have a negative number minus another number, do you add or subtract?</i>	Schema involved

3	Decontextualized math problem: <i>Ok, don't put all that other stuff. What if it was just 16/20. How would you reduce it?</i>	Decontextualized math problem: <i>Now let's change the integers to monomials with variables. So then how would we reduce $15xy^2z^4/25x^3y$?</i>	Low similarity
4	Decontextualized math problem: <i>How would you multiply these? $(x + 2y)(x + y)$</i>	Decontextualized math problem: <i>In that case, how would you multiply $(5x + y)(x + 3y)$</i>	High similarity

Figure 2: Analogy structure and surface similarity

Table 2 shows the frequencies of the surface similarity between analogy sources and targets. There were no significant frequency difference among the four categories, $\chi^2(3) = 3.058 p = .3$, indicating that all four types of analogy constructions were regularly used.

Table 2: Surface similarity between source and target

SURFACE SIMILARITY	FREQUENCY
Schema involved	28
Far distance// outside-math source/target involved	19
Low surface similarity	31
High surface similarity	25
Total	103

4. Function

The function of each analogy unit was coded to examine the context and purpose for analogy use. Primarily, this code examined whether the analogy was directed toward explaining a concept, a procedure, or a combination of the two. Additionally, a separate code marked whether the analogy was implemented following evidence of a student having trouble with a problem or concept.

	Mathematical Function	Paraphrased Examples
Code 1	Being a math student.	<i>Remove the parentheses, very carefully. Kind of like if you were a bomb squad called in to diffuse a bomb. If you mess up the first step, the whole problem will blow up in your face at the end!</i>
Code 2	Teach concepts only.	<i>When you're adding fractions, think about your denominators as units, like centimeters or feet. When you add length, the units must be the same in order to add them.</i>
Code 3	Teach concepts and procedures	<i>Ok do you remember how we found the perimeter and area of polygons last week? This time it is the same concept but we are going to use the formulas to solve for circumference and area of a circle.</i>
Code 4	Teach procedures only.	<i>What were the steps we used to solve the last example? OK lets do the same thing in this problem. First lets factor the numerator and denominator and then we'll see what we can cancel..</i>

Figure 3: Analogy Function

The mathematical function of each identified analogy revealed that some functions were more frequent than others $\chi^2(3) = 20.1, p < .001$. The raw frequencies are shown in Table 3. Teachers were most likely to use analogies to teach procedures only. The frequency distribution may be related to the tendency of US teachers to teach more procedures than concepts during a single lesson (Stigler et al, 1998).

Table 3: Frequency of mathematical analogy functions.

FUNCTION	FREQUENCY
Being a math student	12
Concepts only	19
Concepts and Procedures	30
Procedures only	42
Total	103

We were interested in whether the function or purpose of the analogy was related to the type of analogy produced. Two steps were taken to investigate this question. First, a Pearson chi square was performed to compare analogy function with the structure of source generated. This test revealed that there is a significant relationship between the source generated and the structure of each analogy, $\chi^2(12) = 35.8, p < .001$.

Figure 4: Source structure according to math teaching function.

Second, in order to determine whether the structure of the whole analogy is related to the function, a Pearson chi square was performed to compare the surface similarity between the source and target of each analogy with its function. This test revealed that there was a significant relationship between these variables, $\chi^2(3) = 37.5, p < .0001$. Far distance analogies were almost exclusively used to explain concepts or concepts paired with procedures. In contrast, relational mappings with high surface similarity between sources and targets were almost exclusively used to teach procedures only. Schemas were more likely to be used in analogies demonstrating concepts, but were also regularly used to teach procedures. Low surface similarity analogies, and mappings based on a decontextualized mathematics object, were used more frequently to teach procedures than concepts.

Figure 5: Surface similarity according to math teaching function.

Discussion

The present findings suggest that analogies are regularly produced in US mathematics classrooms, and are generated in reliable structural patterns. These patterns vary as a function of the immediate context and purpose of the analogy. The specific nature of these relationships suggest that analogy generation is highly constrained and organized by the goal of the analogy. When the goal of the analogy was to teach conceptual information, teachers were more likely to use distance analogies, schemas, and lower surface similarity than when they were teaching math procedures alone.

Patterns of analogy usage also revealed interesting associations between teachers' analogy practices and previous research. Teachers frequently presented multiple sources, techniques that have been demonstrated to facilitate schema acquisition and transfer (e.g., Gick & Holyoak, 1983). Thus it is possible that teachers may be using intuitive theories of analogy to guide their analogy production towards an effective teaching tool.

In addition, teachers provided substantial structure for each analogy, perhaps because they are aware that noticing analogies is a difficult task, as has been frequently demonstrated experimentally. While the teachers' assistance makes the analogy more likely to be completed successfully than if students were responsible for generating more components, however, this design provides little information to the teacher about whether students are actually performing analogical reasoning when analogies are produced in this way. Although teachers frequently asked students to participate in producing analogies, they may not be aware that the way most students participate does not require that they perform higher order comparative reasoning.

Further, educational research suggests that enabling students to generate predictions and inferences about unknown problem types can be highly beneficial for their transfer performance (e.g., Carpenter, Fennema, Fuson & Hiebert, Human, Murray, Olivier & Werne, 1999). These findings therefore suggest that teachers might be reducing the learning benefits of analogy by highly structuring the comparisons for students. This is an empirical question that is currently under investigation.

Category Size and Category-Based Induction

Aidan Feeney & David R. Gardiner

Abstract

In this paper we investigate the role of category size in category-based induction. In a series of three experiments we asked participants about the strength of inductive inferences from arbitrary subordinate categories to their superordinates. We show that people use both subordinate and superordinate category size as a cue in category-based induction (Experiments 1 & 2). However, the results of Experiment 3 show that the effect of subordinate category size is smaller when the categories are said to be similar than when said to be dissimilar. On the basis of this result we suggest that people use category size as an indication of how much uncertainty remains concerning the superordinate rather than as a means of assessing how representative the category is as a sample of the superordinate. We conclude with a discussion of possible strategies for inductive reasoning.

One of the functions of categories is to promote inductive inference. Knowing that one set of instances possesses a certain feature allows us to consider whether other sets are also likely to possess the same feature. For example, knowledge that all of the chairs in the lecture room we are currently in are made of plastic will assist us in making a prediction about the chairs in the lecture theatre next door, the cafeteria at the end of the corridor and the provost's office. The experiments to be reported in this paper were all concerned with the role played by information about category-size in such inductive inferences. They ask whether participants are more likely to project a property if it is possessed by instances of a larger category than of a smaller category and whether people are more confident about conclusions concerning large or small groups. Furthermore, if people do turn out to be sensitive to size cues in this manner, what kind of reasoning underlies their use of such cues? As we will see below, there are a variety of ways in which category size might influence people's judgements of inductive strength.

Other researchers have been interested in induction based on categories and there are several models of categorical induction in the literature all designed to capture between 12 and 15 phenomena (for an excellent review, see Heit, 2000). One factor that is common to all of these models is inter-category similarity (Osherson et al, 1990) or featural overlap between categories (Sloman, 1993). To illustrate

how similarity might affect the strength of an inductive inference consider the arguments below where the statement above the line is a premise and the statement below the line is a conclusion. With arguments of this type participants are asked to assume the premise to be true and to evaluate the degree to which it supports the conclusion.

Robins have an ulnar artery

Thrushes have an ulnar artery

Argument 1

Robins have an ulnar artery

Flamingos have an ulnar artery

Argument 2

As the categories in Argument 1 are more similar than those in Argument 2, people will judge the former to be stronger than the latter. Where the conclusion category is superordinate to the premise category, as in Argument 3 below, the degree to which the premise category is typical of the superordinate category informs people's judgements of inductive strength (see Rips, 1975).

Robins have an ulnar artery

Birds have an ulnar artery

Argument 3

A second factor which, in at least one model of category-based induction, impacts upon judgements of argument strength is 'coverage' (Osherson et al, 1990). Coverage is the degree to which the premise categories are similar to instances of the conclusion category (or, in cases where the conclusion category is not superordinate to the premise categories, to instances of the nearest superordinate category containing both premise and conclusion categories). So, for example, Argument 4 below would normally result in greater ratings of inductive strength than would Argument 5.

German Shepherds produce phagocytes

Poodles produce phagocytes

All dogs produce phagocytes

Argument 4

German shepherds produce phagocytes

Dobermans produce phagocytes

All dogs produce phagocytes

Argument 5

As the premise categories in Argument 4 are similar to a greater range of instances of the conclusion category than are the premise categories in Argument 5, the former is judged to be stronger than the latter. In general, the more diverse are the premise categories, the stronger is the argument (although for exceptions see Sloman, 1993).

There are several things to note about much of the existing work on category-based induction. First, although rarely formally contrasted with normative models of induction (for an exception see Heit, 1998), many of the effects in the literature have an intuitively strong normative basis. For example, both effects of similarity and coverage might be expected under the assumption that participants are sensitive to the representativeness of the samples about which they have some information. Samples that are either similar to, or typical of, the population to which the property will be projected, are, intuitively at least, more representative of that population. Similarly, diverse sets of premises intuitively seem to be more representative of the premises than are non-diverse premises.

A second characteristic of previous work on category-based induction is that researchers have been interested in investigating the effects of category knowledge on inductive judgements concerning natural kinds. As it is not normally possible to know the size of many naturally occurring categories (for example, how many members are there of the category 'bird?') research has tended to concentrate on the role played by inter-category relationships. This may be contrasted with work on, for example, statistical judgement where both the a priori probabilities of the hypotheses as well as the probability of the evidence given each hypothesis has been manipulated. By presenting participants with problems concerning arbitrary categories in which category size was manipulated, the work to be described here attempted to address the role that category size plays in category-based induction.

Category Size and Category-Based Induction

Consider the following scenario:

672 people work in a 10 story office block. Of these, 313 work on floor 2 and 35 work on floor 7.

Given this scenario, which of these arguments is the strongest?

All 313 people who work on floor 2 have an identity number beginning with the letter Z.

All 672 people who work in the office block have an identity number beginning with the letter Z. Argument 6

All 35 people who work on floor 7 have an identity number beginning with the letter Z.

All 672 people who work in the office block have an identity number beginning with the letter Z. Argument 7

There are at least two reasons for preferring Argument 6 to Argument 7. The first line of reasoning is that the sample size in Argument 6 is larger than that in Argument 7. As larger samples are held to be more representative of the populations from which they are drawn than are small samples, Argument 6 is stronger than Argument 7 (for a recent discussion of the psychological literatures on sensitivity to sample size see Sedlmeier & Gigerenzer, 1997, and Keren & Lewis, 2000). However, since Nisbett et al's (1983) work on statistical heuristics in induction, it has been known that the variability of the feature being projected interacts with sample size to determine inductive strength. For example, Nisbett et al found that only a very small sample was required for participants to project features for which there is little within category variability (e.g. colour in a specific species of bird) whereas a much larger sample was required for the projection of more variable features. In the scenario above, the information that people work on different floors may suggest variability in staff identity numbers. That is, if category structure is made salient by a scenario, sample size may not be considered relevant in determining the strength of the inference.

The type of reasoning described above relies on indirect inference. That is, an inference about characteristic of a population is made on the basis of evidence about the prevalence of that characteristic amongst members of a sample. A less sophisticated, but more direct, way of making the inference is to think about the sample as a proportion of the population. Thus, if a large proportion of the population is known to possess the characteristic, then there is less uncertainty about the remaining members of the population and hence, a greater probability that the characteristic is universally possessed.

If we find that participants are sensitive to category size when asked to evaluate category-based inductive inferences, then the question arises as to what form of statistical reasoning underlies that sensitivity. The first two experiments to be reported here were designed to investigate premise and conclusion categories as cues to inductive reasoning whilst the final experiment was designed to compare contrasting accounts of any category size effect.

Experiment 1

Method

A total of 40 participants from the undergraduate population of the University of Durham (Stockton campus) took part in this experiment. Of these, 11 were male and 29 were female. The average age of participants was 22 years.

Experiment 1 had an entirely within participants design. The dependent variable was the number of problems for which participants chose as strongest the argument

concerning a large premise category. Each participant received a set of instructions and eight reasoning problems. Each problem described a superordinate category and two subordinate categories. The absolute size of each category was described such that the *Large* subordinate category was 25-40%, and the *Small* subordinate category 5-8%, of the size of the superordinate category. Participants received problems such as the following:

Extensive research has shown that there are several strains of the dreaded, and always fatal, Xanthrax virus. 1,000 people are known to have died from the virus. One form of the virus is Strain 6 from which 300 people have died. Another form is Strain 3 from which 60 people have died.

and were then asked to indicate which of two arguments was the stronger. These arguments consisted of a premise, concerning one or other of the subordinate categories, and a conclusion concerning the superordinate category:

Xanthrax Strain 6 produces a blotchy rash in sufferers
All 1,000 Xanthrax fatalities displayed a blotchy rash

Xanthrax Strain 3 produces a blotchy rash in sufferers
All 1,000 Xanthrax fatalities displayed a blotchy rash

The order in which the arguments appeared was controlled whilst the eight problems appeared in one of eight randomly determined orders. The other seven problems concerned books in a library, articles from several issues of a journal, the age of trees in a forest, houses sold by an estate agent, workers in an office block, characteristics of historical artefacts and works of art.

Results and Discussion

As expected, participants displayed a marked preference for arguments involving the large subordinate category. Out of a maximum of eight, the mean number of such arguments selected as being stronger was 6.13 (S.D. = 1.99). The difference between the number of large subordinate category arguments that were selected as stronger and the number that would be predicted by chance was statistically significant across all problem contents ($t(40) = 6.76, p < .001$). This preference for large premise categories was also statistically significant in all eight problem contents ($\chi^2(1) > 8$ in 7 out of the eight cases). Response frequencies, broken down by content, are displayed in Table 1.

The results of Experiment 1 confirm our intuition that participants are more likely to project a property to a superordinate category from a large rather than a small

subordinate. In Experiment 2 we kept subordinate category size constant and, instead, manipulated the size of the

Table 1: Large and Small argument selection from Experiment 1.

Problem Content	Subordinate Category	
	Small	Large
Disease	13	27
Library	8	32
Housing	11	29
Forest	10	30
Journal	10	30
Office Block	10	30
Artefacts	7	33
Gallery	6	34

superordinate category. Our strong intuition was that participants would be happiest projecting a feature to a small, rather than a large, category. An analogous effect exists in the literature (Osherson et al, 1990) where participants have been demonstrated to prefer projections to lower level, and hence smaller, categories.

A second aim of this experiment was to demonstrate category size effects in a between participants design. The literature on base rate neglect (see Koehler, 1996) contains demonstrations that participants are more likely to take the base rate into account when base rate is manipulated within participants. Hence, in Experiment 2 we wished to investigate whether participants would take category size into account in a between participant design.

Experiment 2

Method

The experiment had a 2 x 3 mixed design. Population size was manipulated between participants whilst each participant received three different problems asking them to rate the strength of an inductive argument.

A total of 116 participants from the undergraduate population at the University of Durham (Stockton Campus) took part in this experiment. Of these, 58 were male and 58 were female. The average age of participants was 21 years.

Participants received a booklet containing a set of instructions followed by three reasoning tasks. These tasks asked participants to evaluate the strength of arguments projecting a feature possessed by a subordinate category to all members of its superordinate. The problems concerned sub-types of a disease, individual production lines in a factory, and different variants of a plastic. Participants were

requested to rate the strength of the arguments on a 1-10 scale (very weak – very strong).

In cases where the superordinate category was small, the subordinate category accounted for between 45 and 55% of the superordinate. When the superordinate category was large, subordinate categories accounted for between 5 and 8% of the larger category. Importantly, only the size of the superordinate category was altered in this experiment. Approximately equal numbers of participants attempted the problems in each of the six possible orders.

Results and Discussion

The means and standard deviations from this experiment are presented in Table 2. A 2x3 Anova analysis revealed a significant effect of population size on the strength ratings assigned to arguments ($F(1, 114) = 5.32$, $MSE = 9.98$, $p < .03$). As expected, the mean ratings for large population arguments (mean = 2.81, $S.D. = 1.68$) were significantly smaller than for the small population arguments (mean = 3.59, $S.D. = 1.96$). Neither of the other effects tested by the analysis were significant.

Table 2: Means and standard deviations from Experiment 2.

Condition	Content		
	Disease	Factory	Plastic
Large	3.84 (2.41)	3.14 (2.23)	3.79 (2.71)
Small	2.74 (2.07)	2.84 (2.07)	2.84 (1.96)
	3.29 (2.31)	2.99 (2.14)	3.32 (2.40)

As expected, participants rated arguments projecting features to small conclusion categories more highly than they did arguments concerning large conclusion categories. However, one striking aspect of these results is that mean ratings of argument strength were very low. It would appear that, at least in a between participants design, making subordinate categories salient in the scenario causes participants to doubt the conclusion regardless of conclusion category size. One possible reason for this is that participants may expect there to be differences between subordinate categories. This expectation may contribute to their unwillingness to project a feature to the superordinate on the basis of evidence concerning only one subordinate. In Experiment 3 we investigated the effects of explicit information about similarities and dissimilarities between subordinate categories on ratings of inductive strength.

Experiment 3

Experiments 1 and 2 have demonstrated that participants are sensitive to both subordinate and superordinate category when evaluating the strength of inductive arguments. In Experiment 3 we attempted to contrast two possible

accounts of people's use of category size as a cue for induction.

The first account we considered was that people's judgements are affected by subordinate category size because they use a sample size heuristic (see Nisbett et al, 1983). That is, people realise that larger samples are more representative of the population from which they are drawn than are smaller samples. Alternatively, people may reason that a large subordinate leaves a smaller proportion of the superordinate unaccounted for than a small subordinate and hence, makes for a stronger argument.

To test these alternative accounts we gave one group of participants reason to believe that all subordinate categories in the domain were similar whilst telling another group that they were dissimilar. Our reasoning was that 'similar' problems should result in fewer attributions of variability to the superordinate category. If participants were cautious in using a sample size heuristic in Experiment 1 due to worries about the representativeness of the sample, then for 'similar' problems participants in this experiment should be less cautious and a greater effect of category size should be observed. On the other hand, 'dissimilar' problems should produce even more caution and a smaller effect of category size.

An alternative hypothesis is that the effect of category size in Experiment 1 may have been due to an assumption that the subordinate category was unrepresentative of the superordinate. That is, participants may have been unwilling to project a property to the superordinate because the subordinate category for which information was available may not have 'covered' the superordinate category. Accordingly, participants may have endorsed inferences from large premise categories more strongly because large premise categories leave fewer cases unaccounted for in the conclusion category. Thus, telling participants that the subordinate categories in the scenario are similar may cause them to rely less on category size as a cue and to assign higher ratings of inductive strength regardless of category size. Explicitly telling them that members of the superordinate are dissimilar may lead them to rely even more heavily on sample size.

Method

Eight male and 52 female undergraduate students (average age 27 years) from the University of Durham's Stockton Campus took part in this experiment which had a 2 x 2 entirely within participants design. The factors manipulated were the similarity said to hold between subordinate categories in each of the problems (similar vs. dissimilar) and the size of the subordinate category (large vs. small).

Each participant received a nine-page booklet comprising a set of instructions and eight inductive reasoning problems.

In each of these problems participants were told that instances of a subordinate category possessed a feature and were asked to evaluate the strength of an argument projecting this feature to all members of the superordinate category. The problems concerned workers in an office block, symptoms of a disease, features of handmade chairs, materials used by an engine manufacturer, properties of a type of plastic, the type of material used in indigenous art, production lines in a factory, and stock at a fish farm. Each participant received one version of each problem and two problems in each condition of the experiment. Each problem content appeared equally often in each condition of the experiment.

The problems were designed so that the large subordinate category was 45-55% of the size of the superordinate category, whilst the small subordinate category contained 5-8% of the superordinate population. To achieve the similarity manipulation participants were explicitly told that some similarity/dissimilarity existed between all members of the superordinate category. For example, in the office block problem participants were told that the workers either worked for the same, or different, divisions of a company.

Results and Discussion

As participants completed two problems per condition of the design, we calculated a mean score per condition for each participant. We carried out a 2 x 2 entirely within participants ANOVA on this data, the means from which may be seen in Figure 1. Our similarity manipulation had a highly significant effect upon the ratings of argument strength ($F(1, 59) = 24.70$, $MSE = 10.38$, $p < .001$). Mean ratings of argument strength were higher for categories containing similar members (8.15) than for categories containing dissimilar members (6.08). This finding replicates previous work (e.g. Nisbett et al, 1983) suggesting that within category variability significantly affects people's willingness to project a property from a sample to a population.

Figure 1: Interaction between Category Size and Similarity from Experiment 3

Our category size manipulation also had a significant effect on ratings of argument strength ($F(1, 59) = 6.03$, $MSE = 7.19$, $p < .02$). Arguments involving the large subordinate category were rated as stronger (7.54) than those involving the small subordinate (6.69). Although the interaction between these factors did not approach significance ($F(1, 59) = .34$, $MSE = 8.21$, $p > .5$), planned comparisons revealed a significant effect of category size when category members were said to be dissimilar but not when they were said to be similar.

When participants are explicitly told that the members of the superordinate category are similar, premise category size ceases to have a significant effect on judgements of inductive strength. Instead, it would appear that category size is more important under conditions where 'indirect' inductive inference from a subordinate to a superordinate is likely to be unsafe. This suggests that category size functions as an indicator of the number of cases for which uncertainty remains.

General Discussion

Our finding, that category size acts as a cue in category-based inductive inference, is entirely novel (if not entirely unexpected). Likewise, the finding that the effect of category size decreases when participants are explicitly told that subordinate categories are similar is also novel. We will discuss possible interpretations of these findings and their implications for the question of strategy use for induction.

The results of Experiment 3 might be regarded as being consistent with Nisbett et al's findings as in their study participants were found to be insensitive to sample size when the property that they were required to project was unlikely to vary. Similarly, our participants were also relatively insensitive to sample size when told that there were similarities between subordinate categories. It might even be argued that participants' greater sensitivity to sample size in the dissimilar condition is also consistent with Nisbett et al's results and is evidence that participants realised that in conditions of variability, a large sample is safer.

We are unsure about this reading of the results because we find it implausible that participants told that there were dissimilarities between subordinate categories should consider a bigger subordinate category more likely to be representative of the population than a smaller subordinate. We find it much more plausible that participants attributed greater strength to arguments that accounted for the most population members. It is plausible, however, that in the similar condition, participants projected features to the population on the basis of characteristics of the sample. Even in the small category size condition, premise categories always had more than 20 members. This figure

was chosen as 20 was the largest sample size given to participants in Nisbett et al's experiment. Given the existence of a subordinate category structure, participants may have considered the increase in inductive strength from small to larger premise categories to be insubstantial.

We contend that our results suggest that people are flexible in the strategies that they adopt for inductive inference. In conditions of low variability, people will project properties to a population on the basis of the characteristics of a sample. However, where high variability exists, people may be more likely to base their judgements of inductive strength on the number of cases outstanding.

The 'direct' strategy is a very interesting one, partly because it has been somewhat neglected in the literature (although see Evans & Dusoïr, 1977). The conditions for its application are population size being both finite and approximately known. In addition, we suspect that a 'direct' strategy will be used in conditions where the population is small. This is because indirect induction only becomes necessary where the population is large or infinite and it is difficult, or impossible, to check all members. With small populations a direct strategy based on checking as many members as possible is more tractable.

Evidence that group size can affect how people perform induction comes from Wang (1996) who showed that the demonstration of classic framing effects depends on the size of the group being reasoned about. His explanation for this finding is that we possess social-group domain-specific reasoning abilities. As Wang only gave scenarios concerning social groups to his participants, we are unwilling to subscribe to the notion of social-group domain-specific abilities. However, we agree that the human species is likely to have made inferences about relatively small populations throughout most of its history. In addition, formal notions of induction evolved relatively recently (see Gigerenzer et al, 1989), most probably in response to a need for safe inferences about population whose size was unknowable or infinite. Although the 'direct' strategy is primitive when compared to more 'indirect' forms of induction, such a strategy may work very well with small populations.

Why Example Fading Works: A Qualitative Analysis Using Cascade

Eric S. Fleischman (esfleisc@colby.edu)

Randolph M. Jones* (rjones@colby.edu)

Department of Computer Science, Colby College, 5830 Mayflower Hill Drive
Waterville, ME 04901-8858 USA

Abstract

"Faded" examples are example problems that provide a solution, but first require students to generate a portion of the solution themselves. Empirical studies have shown that such examples can be more effective teaching aids than completely worked examples that require no work from the student. Cascade is a model of problem-solving skill acquisition that was originally developed to explain other empirical regularities associated with human problem solving and learning, most notably the self-explanation effect. Past research demonstrated that Cascade might also explain the mechanisms underlying the effectiveness of example fading. This paper analyzes new protocol data, and finds that it is consistent with predictions derived from Cascade.

Overview

Renkl, Atkinson, and Maier (2000) empirically demonstrated the qualitative result that, when learning problem-solving skills, students studying a series of "faded" examples show improved post-test performance over students studying only completely worked examples. Jones and Fleischman (2001) argue that this result can be explained by Cascade (VanLehn, Jones, & Chi, 1991), a computational model of problem-solving skill acquisition. Cascade was originally developed to understand the mechanisms of the self-explanation effect (Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Pirolli & Anderson, 1985). Jones and Fleischman demonstrated that the mechanisms underlying self-explanation might also explain the effectiveness of studying faded examples. Although they showed that Cascade is consistent with the fading result, the explanation involved assumptions that had not yet been tested empirically. Therefore Jones and Fleischman (2001) finished with a small set of predictions and suggestions for new experiments to confirm or dispute Cascade's account. Since that time, Renkl, Atkinson, and their colleagues have run additional experiments, collecting detailed transcripts of subjects studying two types of faded sequences of problems. Although the experiments are not yet complete, we have been able to perform a qualitative analysis of the protocol data for eight of the subjects. Additionally, we have fine-tuned Cascade's knowledge base (but not its underlying mechanisms) to more faithfully model the current data. This paper reports the result of using Cascade to develop a qualitative analysis of the eight subjects. The primary result is that the findings remain

consistent with Cascade's account of example fading, as well as the predictions made by Jones and Fleischman (2001).

Background

Years of research have demonstrated effective techniques for teaching students problem-solving skills in a variety of task domains. In particular, a number of studies show that students benefit from being given a series of completely worked example problems, followed by a series of unworked practice problems (e.g., Chi et al., 1989; Pirolli & Anderson, 1985; Renkl, 1997, VanLehn, 1996). Other studies show that the effectiveness of such a curriculum depends in part on the willingness of the students to explain the worked examples to themselves in detail, rather than simply giving the examples a superficial read (Chi et al., 1989; Fergusson-Hessler & de Jong, 1990; Pirolli & Bielaczyc, 1989). VanLehn and Jones (1993a, 1993b; VanLehn et al., 1991) developed Cascade in order to determine the cognitive mechanisms behind this *self-explanation effect*. In essence, Cascade suggests that thorough study of worked examples help students consciously expose and patch gaps in their task knowledge. In addition, self-explanation provides contextual memories that can guide future problem solving by analogy to familiar examples.

Subsequent experiments by Renkl et al. (2000) suggest that student learning can improve even further by *fading* a curriculum from fully worked examples to partially worked examples. The partially worked examples provide a complete solution to the problem (as with fully worked examples), but first require students to derive one or more steps on their own. This in turn requires the students to understand the rest of the example in at least enough detail to be able to attempt a solution.

Jones and Fleischman (2001) argue that the reason faded examples improve learning is that they retain much of the guidance provided by the context of a solved example, but they force the students to work on particular parts of the problem, in turn possibly forcing them to expose and patch knowledge gaps. This is in contrast to studying completely worked examples, where it is basically up to the students to decide whether they are going to put any effort into understanding the examples (because the students are not required to produce any answers in that case). This argument came directly from the assumption that Cascade is

* The second author is also affiliated with Soar Technology, Inc.

an accurate model of human problem solving and learning (at this level of abstraction).

Jones and Fleischman ran Cascade on a mock "faded" curriculum in order to demonstrate the plausibility of their hypothesis. This exercise confirmed that the proposed explanation is a sufficient account of the general fading results, but the explanation rests on a number of assumptions that had not yet been confirmed by empirical data. The first assumption was that the classical physics problem domain (implemented in Cascade and studied by Chi et al., 1989) is sufficiently similar to computing simple probabilities (studied by Renkl et al., 2000). The second assumption was that Cascade's underlying processes accurately match what subjects do when learning from faded examples. Data had simply not yet been collected to argue this point either way. Thus, Jones and Fleischman (2001) presented three specific predictions to be confirmed or denied by subsequent empirical research:

1. "Faded examples cause effective learning by forcing the student to encounter and overcome an impasse."
2. There is likely "...at least some benefit to example fading from the learning of search control knowledge."
3. "The primary benefit of a faded example is that it forces the student to process parts of the example that they might otherwise ignore."

They also suggested that these predictions be tested with new experiments that include the collection of protocol data.

The current work tackles both of these issues. To begin with, Renkl and Atkinson (and their colleagues) have initiated an additional study to collect more detailed subject data, including transcribed talk-aloud protocols generated by the subjects while studying and solving problems. Although their experiment and analysis is not yet complete, they provided us with eight initial transcripts, enabling us to generate a partial coding that tests the predictions listed above.

We have also generated a new task knowledge base for computing probabilities, so Cascade can solve precisely the same problems given to the subjects in the new experiments. This allows us to remove a model assumption, and verify the Cascade results with a more accurate match to the data. The next section describes the methods we used to generate the new knowledge base and encode the protocols. The following sections present the results of those activities in more detail.

Methods

Given the study material presented to the experimental subjects, we first performed a thorough task analysis. This involved identifying the probability equations required for solving the set of study problems. This set serves as the target knowledge base that we would expect a "perfect learner" to have acquired after complete study of the curriculum. The task analysis allowed us to replace Cascade's physics task knowledge with task knowledge

about computing probabilities. It is important to note that we only changed Cascade's task knowledge. We did not change any of the underlying problem-solving or learning mechanisms built into Cascade. Once we defined the target knowledge base, we represented each problem as a set of given and sought quantities, using Cascade's representation language within Prolog.

After doing the task analysis, we ran Cascade on each problem in order to perform a content analysis. The content analysis records the required equations for each solution. This allows us to predict interactions between performance on separate problems by a single subject. For example, if a subject fails to use an identified equation in one problem (as suggested by an error combined with protocol evidence), but then correctly solves a subsequent problem that requires the same equation, we can safely hypothesize that some sort of learning took place even if there is no direct evidence of a learning episode in the protocol transcript. This helps us track learning across a series of problems. The content analysis also helps constrain the encoding of the subject protocols. In the face of ambiguous utterances that lead to a correct solution, we can generally infer which equations the subject must have used correctly.

Our final task was to encode the subject protocols for behavior episodes relevant to the predictions reported above. Future work (when all subject protocols are available) will contain thorough quantitative analyses of various protocol encodings. For the current effort, however, we performed a qualitative analysis, looking for general trends in the data. The goal was to investigate whether there were any relationships between example fading and learning, the use of analogies for search control, and the generation of self-explanations. We constrained the protocol encoding by performing a goal decomposition to match each subject protocol. Running Cascade on the same problems generates similar goal decompositions, which we can then use to inform the coding process.

Task and Content Analysis

As mentioned above, the task analysis determined all of the equations, or knowledge chunks, required to solve the set of probability problems from the empirical study. We did not include more basic arithmetic reasoning (such as addition, multiplication, and the ability to isolate variables) in the analysis. This is because, for the domains Cascade has been used to study so far, it simplifies the model to assume that subjects have well rehearsed knowledge of these tasks. For the problems in question, we identified twelve distinct, required equations. Some of the equations compute simple probabilities by dividing the cardinality of various sets of objects. The task knowledge includes cases for choosing objects at random with and without replacement. The target knowledge base also includes various equations for combining probabilities. These include the special multiplication rule

$$P(e1 \text{ and } e2) = P(e1) \times P(e2)$$

the addition rule

<p>So I have a total of 12 bottles and there are 4 that are turned into vinegar. So a total of 4 vinegar and 8 drinkable. Probability of vinegar is 1/3 and drinkable is 2/3. Now if we take one then we're left with...There is a 1 in 3 chance that that will be vinegar...</p>	<p>S: value(p(event a)) S: solve(p(event) = size(selectionpool) / size(totalpool)) S: value(size(selectionpool)) F: value(size(selectionpool)) = 4 S: value(size(totalpool)) F: value(size(totalpool)) = 12 F: solve(p(event) = size(selectionpool) / size(totalpool)): 1/3 F: value(p(event a)) = 1/3</p>

Table 1. A protocol excerpt and its corresponding analysis in the form of a Cascade trace.

$P(e1 \text{ or } e2) = P(e1) + P(e2) - P(e1 \text{ and } e2)$
and the subtraction rule

$$P(\text{not } e) = 1 - P(e).$$

It is worth comparing some features of this domain with classical mechanics, the domain used in previous studies with Cascade. The physics and probabilities domains share the feature of involving mostly symbolic problem-solving skills, which we feel is the defining characteristic that allows Cascade to model both well. However, there are also some potentially significant differences between the two domains.

To begin with, the target knowledge base for computing probabilities is much smaller than the physics knowledge base. In contrast to the current set of 12 equations, Cascade required explicit representation of 62 separate chunks of knowledge for classical physics. Another significant difference is that subjects often relied on common-sense reasoning to explain and learn physics skills. Thus, the Cascade model for physics included a number of general common-sense rules that could be used to guide the learning of correct (and sometimes incorrect) physics knowledge. In contrast, there seems to be much less opportunity to generate common-sense explanations for the rules of probabilities (although there are certainly some). In the protocols we have studied so far, subjects generally made little use of common-sense principles when they got stuck.

To perform the content analysis, we encoded the problems provided by Renkl and Atkinson into Cascade's representation. This essentially involved translating the problems' given and sought quantities into a Prolog-style predicate representation. Once complete, we ran Cascade to ensure it could solve each problem with the complete knowledge base. Each problem run generated an execution trace that provides explicit detail about which equations are necessary to solve each problem. With these tools in hand, we proceeded to analyze each subject protocol to track the usage of individual equations, self-explanation behavior, the use of analogy to guide problem solving, and learning.

Protocol Analysis

The basic approach to the protocol analysis was to assume that Cascade provides an accurate model of each subject's behavior and then to look for inconsistencies. We patterned this approach after Jones and VanLehn's (1992) evaluation of Cascade's ability to model the fine-grained behavior of individual subjects studying and solving physics problems.

For each subject-problem pair, we generated the hypothetical solution trace that Cascade would have to generate in order to produce the utterances observed in the subject. We allowed ourselves to tune the trace only by assuming that Cascade has missing or incorrect knowledge about computing probabilities. Any other discrepancies between Cascade and the protocol data are marked against Cascade's ability to explain the subject's performance. Table 1 presents an example protocol excerpt and the corresponding Cascade trace that matches the internal behavior suggested by the subject's utterances.

We constructed Cascade-like traces for a number of problems, and used those results to guide the rest of our protocol analysis. Recall that the predictions presented by Jones and Fleischman (2001) focused on self-explanation, forced impasses, knowledge acquisition from impasses, and knowledge tuning. Thus, our protocol analysis focuses on these three issues.

Self-Explanation

For Cascade's account of fading to be correct, it must mean that subjects tend to generate more self-explanations (or problem-solving activity) for faded examples than they do for completely worked examples. This prediction is borne out in the protocol data we examined. Subjects rarely engaged in self-explaining on fully worked examples. Subjects were much more engaged in the faded examples, presumably because the faded examples demanded them to generate some kind of answer. The protocols show evidence that sometimes even this was not enough to ensure self explanation. Sometimes, subjects would simply "click through" the faded portions of the examples, and skip on to the solutions. For example, after revealing a solution step, one subject simply said "Boy...summmsummm...I don't know this right now," and proceeded to the next step. However, there were certainly many more instances of self-explanation for faded examples than there were for completely worked examples.

Impasses

Subjects encountered impasses during fully worked examples even more rarely than they bothered to self-explain the examples. This is because a subject cannot experience an impasse without first engaging in some self-explanation. However, subjects experienced many impasses when working on faded examples. This is because, if the

subject made a mistake, they received relatively immediate feedback by then being shown the correct solution step. If the subject bothered to read the revealed solution, they would have to acknowledge a discrepancy and go back to refigure things. The following excerpt shows an example of a subject first reading a completely worked example (Problem 5) with no impasse, and then working a faded example (Problem 6) that forces an impasse. Both problems require precisely the same set of equations to generate a correct solution.

Problem 5:

S: Okay, let's see here. Probability is $1/10$ time $1/5$, okay, I see how they did it, alright. Probability of stitching and/or color defects is $1/10$ plus $1/5$ minus the total probability that's $1/50$, and that equals (reads aloud) okay, next.

Problem 6:

S: Okay, alright. Now. This is the difference, that's going to be 1 minus the $2/50$ plus the $23/50$, that's going to be, 1 minus okay, $2/50$ or, $2/50$ equals .04, and plus $23/50$ equals .46, now, .46 and .04, give me .50, 1 minus .50 equals .50, so, I'm doing this right, it should be .50, no, okay, alright, let's see, okay, I guess I..., okay, so that's 1 minus that, okay, I see what I did.

In this excerpt, the subject essentially just reads Problem 5 and claims to understand it (which is, paradoxically, a hallmark of subjects that are *not* doing enough self explanation). The subject generates an answer to Problem 6 that they think is correct, but when they reveal the correct solution step they discover they are wrong. This forces an impasse. In this particular excerpt, there is no convincing evidence that the subject actually resolved the impasse and learned the correct solution sequence, but the impasse at least gave them the opportunity. The following sections discuss analysis of actual learning episodes in the protocols.

Knowledge Acquisition

We were surprised to find no obvious episodes of knowledge acquisition in the protocols. That is, we found no evidence that subject were missing entire chunks of knowledge that they were then able to discover in response to an impasse. This was particularly surprising because Jones and Fleischman (2001) assumed a key role for knowledge acquisition episodes during their initial Cascade study with physics problems. It appears that this is a place where differences in the task domains are significant. As mentioned previously, knowledge acquisition episodes were an extremely important part of Cascade's account of the self-explanation effect for the physics domain. However, in all of the protocols for subject computing probabilities, it appears that they already *know* all of the equations they need; they just have not yet learned the right times to *use* them. This is admittedly a subtle distinction that cannot always be verified in the protocol data, so we plan to give it a much closer look in future studies. However, since our

original proposal gave such a large role to knowledge acquisition, we feel we are being conservative by suggesting that there are no knowledge acquisition episodes at all in the current protocol data. There are clearly other types of learning episodes in the data, which we describe below, and we feel that those remain consistent with Cascade's predictions about fading.

Knowledge Tuning

One of the predictions about Cascade's account of fading was that fading enables students to tune knowledge they have already acquired, by allowing them to use it in a useful problem-solving context. In Cascade, all knowledge tuning occurs via a process of analogical search control. Thus, we expect to see subjects learn after they have successfully drawn an analogy between two problems. We observed many such episodes in the current protocol data. The following excerpt provides one of the clearest examples:

Problem 2:

S: ...The chance of it being drinkable is 8 to 11 so the probability of her drinking, probability that the first bottle is vinegar but the second is drinkable, 2 red balls and 2 white balls is 4, probability is $1/2$ so if we multiply $1/3$ times $8/11$ that will be $8/33$...

Problem 2 involves a collection of bottles containing wine and vinegar. However, in the middle of the excerpt, the subject makes an explicit analogical reference to Problem 1, which deals with selecting a particular configuration from a collection of red and white balls. In a subsequent problem that uses precisely the same solution technique, the subject easily solves the problem correctly, without any evidence of an impasse or overt analogical reference.

It seems clear that this particular episode involves knowledge tuning via analogy. There are other episodes of knowledge tuning that are not overtly analogical. The current Cascade model dictates that all knowledge tuning occurs by analogy, but that happens at a low enough cognitive level that it is difficult to prove or disprove. Certainly there are many cognitive theories that posit some sort of similarity-based memory for skills and facts.

There is one aspect of knowledge tuning that Cascade does not model well. Some subject protocols show basically the same pattern as the excerpt above, but the tuning occurs more gradually across 3 or 4 problems. Cascade's knowledge tuning mechanism is more of an all-or-nothing proposition. As soon as Cascade solves one problem by analogy, it can immediately retrieve the same knowledge in similarly structured future problems. This seems to be a clear weakness in the Cascade model. However, it does not invalidate Cascade's basic account of fading. The subject protocols show that the use of analogy occurs more frequently during fading-driven impasses than during the study of completely worked examples.

In prior Cascade studies in the physics domain, there were strong interactions between the knowledge tuning and knowledge acquisition mechanisms (VanLehn & Jones, 1993b). We expect that similar interactions could help

explain the effectiveness of fading examples. However, since we have so far seen no evidence of knowledge acquisition in the current study, it has not been important to analyze potential interactions.

Conclusions

We conclude by reiterating the predictions that Jones and Fleischman (2001) proposed to gather evidence for Cascade's account of the benefit of faded examples:

1. "Faded examples cause effective learning by forcing the student to encounter and overcome an impasse."
2. There is likely "...at least some benefit to example fading from the learning of search control knowledge."
3. "The primary benefit of a faded example is that it forces the student to process parts of the example that they might otherwise ignore."

We feel that our initial analysis of protocol data from Renkl, Atkinson, and colleagues confirms each of these predictions to some extent. The basic effect is strong: students often do not expend much effort on understanding completely worked examples, but fading the examples gives the students a strong impetus to do so. This encouragement to work out portions of the examples leads to more opportunities to identify incorrect (or incorrectly applied) knowledge, which in turn provides opportunities to correct or tune that knowledge. We were surprised to find that knowledge acquisition did not appear to play a significant role in the probabilities task domain. However, future analysis will more closely search for such episodes. In addition, although it makes the model less interesting in some ways, the preponderance of analogical knowledge tuning is entirely consistent with the Cascade model. Since Jones and Fleischman's (2001) original study of fading with Cascade did not focus strongly on knowledge tuning (because it played less of a role in the physics domain), an important future task is to run a thorough set of experiments with Cascade to confirm that knowledge tuning can account for all of the observed improvements in problem-solving skill.

It is also certainly possible that future analysis will uncover data that is inconsistent with Cascade's predictions. With this possibility in mind, our next course of action is to gather even more data and perform a more thorough quantitative analysis. We also expect that we will find some ways in which Cascade should be improved. For example, we already know that the knowledge tuning mechanism should be adjusted to account for more gradual forms of knowledge tuning observed in the subjects. Any further mismatches of the model to the data should also serve to improve our understanding of how humans learn problem-solving skills and, as a consequence, inform how we ought to teach them.

Acknowledgments

This project could not have proceeded without the gracious collaboration of Alexander Renkl and Bob Atkinson, together with their research groups. This work was also made possible by the support of Colby College, particularly the Colby College Senior Scholars program, and Soar Technology, Inc.

Evolution of Gender in Indo-European Languages

Harry E. Foundalis (hfoundal@cs.indiana.edu)

Bloomington, IN 47405 USA

Abstract

In a recent paper, Lera Boroditsky and Lauren A. Schmidt (2000) examined the degree to which the linguistic category of grammatical gender of nouns influences people's perception of the cognitive category of biological gender, or sex. Their conclusion was that English speakers' intuitions about the gender of certain nouns (animals) correlate with the gender assigned to those nouns in languages such as German and Spanish. More important, they found that people's ideas about the putative biological gender (sex) of objects are strongly influenced by the grammatical gender of those objects in their native language. In this study I sought to reproduce Boroditsky and Schmidt's results in order to show that the interpretation they supplied is unwarranted, and that the authors conflate the concepts of biological gender (sex) and "formal gender", which is employed by most Indo-European languages (as opposed to "natural gender", in English). I compare the intuitions of 20 American monolinguals with the statistics of formal gender as it appears in 14 Indo-European languages. Moreover, I discuss the possible origin and evolution of gender in such languages, and suggest an explanation for the relation between grammatical and biological gender.

Introduction

The idea that our native language may shape our thought, in part or in whole, is usually associated with the work of Whorf and Sapir, in what is known as "the Sapir-Whorf hypothesis" (Whorf, 1956). This is an intriguing hypothesis because it implies that different cultures — speaking different languages — may perceive the world in different ways. For example, whereas one culture may differentiate objects on the basis of shape, another culture may differentiate them on the basis of material (Imai and Gentner, 1997), and this may be reflected in the corresponding languages. To what extent, then, does language (and culture) force a person's cognition to perceive the world in one way rather than another?

A possible manifestation of this idea was examined by Boroditsky and Schmidt (henceforth B&S), in studying the way grammatical and biological gender interfere with each other in the minds of native speakers of languages such as Spanish and German. B&S support the idea that a speaker whose language assigns the genders masculine and feminine to nouns —

whether they refer to people, animals, things, or ideas — is bound to subliminally think of an object as having a corresponding biological gender, male or female. (To avoid circumlocutions, I use the word "sex" to refer to biological gender, reserving "gender" for the grammatical category.)

B&S's proposal rests on the assumption that there is an inherent equating of the concepts of gender and sex in such a speaker's mind. So, for example, a young learner of an Indo-European language employing "formal gender" could associate a specific category of nouns discernible only through the behavior of neighboring words (say, the feminine nouns) with a perceptual property of entities of the world (say, the femaleness of individuals), even before encountering the words for "feminine" and "masculine". Although the latter point to a certain relation between gender and sex (which undoubtedly exists), we will see that such an assumption is untenable. First, however, we should briefly review the category of gender as it appears in various languages, in order to understand what it is, and what relation we may expect between the concepts of gender and sex.

Although many people are familiar with gender as it appears in Indo-European languages, the notion of gender as understood by linguists is much more general. As a "definition", I will follow Charles F. Hockett's description: "Genders are classes of nouns reflected in the behavior of associated words" (Hockett, 1958:231). A characterization like this is general enough to encompass all noun categories that linguists call "genders", whether they are labeled "masculine", "feminine", "neuter", "common", or even "class IV".

A language may have two or more classes of nouns that qualify as genders, or it may have none, in which case we say that the language lacks a gender system. Such is the case with several of the major families of Asian languages (e.g., Mandarin Chinese). Tamil, a member of the Dravidian family in south India, divides nouns into "rational" (i.e., people, gods) and "non-rational" (animals, and everything else), and further subdivides rational gender into "masculine" and "feminine" (Corbett, 1991:8–10). Thus, Tamil employs a "natural gender system", which means that given the semantics of a noun we can predict its gender, and vice-versa. English, a Germanic language, has a natural

gender system like Tamil, reflected only in personal, possessive, and reflexive pronouns. There are a few exceptions to semantic association: "she" may be used for a ship or country, "he"/"she" for an animal (of unknown sex), and "it" for downgrading humans (Mathiot and Roberts, 1979). Other languages show a less well-defined assignment based on semantics: Zande, a language spoken mainly in the Democratic Republic of the Congo, assigns nouns generally to four genders: masculine, feminine, animal, and neuter (Corbett, 1991:14). There are, however, about 80 exceptions, including such concepts as heavenly and metal objects, and edible plants, which are placed in the animal gender. Dyirbal, an Australian language, also has four genders, denoted by 'class I, II, III, and IV'. It has been shown (Dixon, 1972:308–12) that male humans and non-human animates belong to class I; female humans, water, fire, and fighting to class II; non-flesh food to class III; and everything else to class IV. Thus, the rules are semantic but non-obvious. However, children learning the language do not appear to learn the gender of nouns individually.

Turning now to typical Indo-European languages, we see an even smaller dependence on semantics. Nouns denoting people — assigned to masculine or feminine gender according to sex — are a minority. The "exceptions" (non-sexed objects assigned to either of those two genders) are the majority, thus making the semantic association a rather useless predictor for the gender of a noun. This fact, as we shall see, is very important for a correct assessment of B&S's work.

B&S's Experiment 1

In their first experiment, B&S investigated whether "the grammatical genders of nouns do in part reflect the properties of their referents" (Boroditsky and Schmidt, 2000:2). If true, they predicted "a correspondence in the assignment of genders across languages, and also a correspondence between Spanish and German genders and English speakers' naive intuitions". Although their testing of the prediction of correspondence across languages was rather inadequate (regarding the number of languages; I improve this test in the present study), they did a more thorough test of the naive intuitions of 15 English speakers, none of whom were familiar with either Spanish or German (though we do not know if they were monolinguals). The subjects were asked to exclusively classify each of 50 animal names and 85 names of artifacts as either masculine or feminine (B&S do not give a list of those words).

Their comparison of gender agreement between Spanish and German yielded a correlation coefficient of $r = 0.21$, $p < 0.05$. This, they termed an "appreciable agreement". Although I would think a value of $r = 0.21$ (hence, $r^2 = 0.04$) indicates a rather appreciable disagreement, B&S pointed out that the two languages

'agreed more on the genders of animals ($r = .39$, $p < .01$), [than] on the genders of artifacts ($r = .10$, $p < .35$)".

To test B&S's hypothesis on the agreement of gender across languages, I examined 84 common nouns in 14 Indo-European languages. The nouns were chosen so that they represented more-or-less common referents: 20 artifacts, 22 natural objects, 20 abstract ideas, and 22 animals. The 14 languages were chosen so that a fairly representative set of the Indo-European family tree was obtained (three Germanic: Dutch, German, Icelandic; four Romance: French, Italian, Spanish, Portuguese; three Slavic: Polish, Russian, Serbo-Croatian; one Celtic: Irish; and also Albanian, Greek, and Kurdish.) Native speakers verified my choices of nouns (originally collected from dictionaries) for all languages but Albanian, Dutch, and Icelandic. The full assignment of genders is given in Appendix A.

The results of my study show that, predictably, the closer languages are in the family tree, the more they agree on gender. Languages as close linguistically as Portuguese and Spanish show a coefficient of determination¹ $r^2 = 0.75$. However, the coefficient between Spanish and German is $r^2 = 0.09$, $p < 0.01$ (so, $r = 0.30$; compare with B&S's $r = 0.21$), and the one between Spanish and Russian is $r^2 = 0.03$, exhibiting a complete uncorrelatedness (see Table 1). Overall, languages that belong to different subfamilies (e.g., a pair formed by a Romance and a Germanic language) show appreciable disagreement. For languages in the same subfamily, the part on which they agree — as given by the coefficient r^2 — is explicable not by reference to any inherent common intuition of people on the sex of things like a book and a tree, but by reference to the fact that Indo-European languages evolved from a common ancestor language, which employed gender, probably one with a strong semantic basis. As languages diverged, so did gender assignments, precisely *because* there is no objective and universal basis on which to decide the gender/sex of "flower", or the idea of "war", or even the words for "bat" and "butterfly". (See Appendix A: each of these words is nearly evenly assigned — close to 50% — between the masculine and feminine genders.) Table 1 shows the coefficients of determination (r^2) between the 14 languages.

B&S's second prediction is that English native speakers' naive intuitions about the gender of nouns

¹ Since I observed no negative correlation, I prefer to use r^2 , the *coefficient of determination*, rather than r , the correlation coefficient, because the former has a natural interpretation, which the latter lacks: r^2 shows the proportion of variation in one population that is explained by the variation in the other population. To be precise, I should employ the non-parametric r_s^2 : *Spearman rank coefficient of determination*, since the populations are highly non-normal. However, in our case differences between r^2 and r_s^2 appear only in the second decimal place, so I will keep referring to r^2 in order to facilitate the comparison with B&S's results.

Table 1: Coefficients of determination (r^2) for the 14 languages, plus English monolinguals ('En', last row).

should show a correspondence with the assignment of gender in other Indo-European languages. To test this prediction I asked 20 monolingual native American English speakers (10 males and 10 females) to assign a gender, either masculine or feminine, to each of the 84 nouns listed in Appendix A. Subjects showed a remarkable consistency among themselves (average standard deviation $s = 0.18$), especially for words that have a natural association with maleness and potency (e.g., hammer, boulder, thunder, attack, war, lion), or with femaleness and beauty (e.g., flower, happiness, love, butterfly). The average assignments of genders by English monolinguals form a 15th population, which was compared against each of the 14 studied languages to determine the degree of correlation. The last row in Table 1 shows the values of r^2 for each case. We see that the opinion of native English speakers on gender shows a very weak correlation with each of the 14 languages, except possibly Kurdish (which can be attributed to statistical error). No negative correlation was observed. The average of all r^2 is $\langle r^2 \rangle = 0.03$. The p -values (indicating linear relationships) are statistically insignificant ($p > 0.05$) for all languages but Dutch, German, and Kurdish. However, it should be noted that the p -values are bound to converge to zero given a large enough sample size. What is important is not *whether* a linear relationship exists, suggested by the p -values, but the *magnitude* of correlation, given by r^2 .

To explain why the correlation between English speakers' intuitions and gender assignment in the 14 studied languages is so weak, we must understand the cognitive processes of gender acquisition in such languages. Young learners of Indo-European languages with formal gender might notice the close correlation between gender and sex *when the noun being referred to is a person* (or even a pet of a known sex). However, learners could not miss noticing the clear *unrelatedness* of gender and sex when the object being referred to is

not an animal, and thus lacks sex. In the young learner's world, the nouns for which gender and sex correlate nicely are a small minority compared to those for which the two notions cannot be correlated (because sex is *not* one of the perceived properties of the object referred to by the noun). The situation is depicted in Figure 1.

Figure 1: Gender vs. sex in 'formal gender' languages

The sizes of the areas in Figure 1 are schematic, but relevant. Assuming the learner's cognitive mechanisms are tuned toward noticing the statistics and learning the regularities of this world, we conclude that the learner of such a language should not find the linguistic category of gender a particularly good predictor of the cognitive percept of sex. We should note that, at an early (pre-school) age, the learner is oblivious to the fact that the name of an observed category of nouns is 'masculine', a word closely associated with maleness, while another category is called 'feminine'; the learner simply notices the categories. Later, during formal education, the suspected (weak) relation between the notions of gender and sex may be reinforced, but it happens at a time when the learner has already acquired the linguistic category of formal gender, and has already noted that, as Figure 1 suggests, gender is not a good predictor of sex, and the two notions are only loosely related.

On the contrary, learners of languages that employ 'natural gender', such as English, notice the close correlation between gender and sex. For such languages, the situation is depicted in Figure 2.

Figure 2: Gender vs. sex in 'natural gender' languages

In this case, the intersection of masculine, feminine, and neuter nouns having the “correct” correlation with the percepts ‘male’, ‘female’, and ‘other’ is large. The close correlation between gender and sex thus turns the percept of sex into a *good predictor* of the grammatical category of gender, and vice-versa. This fact may lead speakers of languages employing natural gender into *conflating* the two ideas, and possibly, as the B&S paper implicitly suggests, thinking that native speakers of languages with formal gender may perform a similar conflation. We should note in passing that one of the meanings of the word ‘gender’ in English is ‘the state of being male, female, or neuter; sex’ (Oxford English Dictionary, 1993). Thus, in English, the question ‘what is your gender?’ is a meaningful one to ask a person. In Greek on the other hand, a typical Indo-European language employing formal gender, the same question (‘*pio eenh to genos sou?*’) is absurd, because it implies the questioned entity is a *noun*—akin to asking in English: ‘what is your declension?’

B&S’s Experiment 2

In their second experiment, B&S attempted to test whether ‘people’s ideas about the genders of objects are strongly influenced by the grammatical genders assigned to these objects in their native language’ (Boroditsky and Schmidt, 2000: Abstract). B&S based their hypothesis on an earlier study (Konishi, 1993) where German and Spanish speakers judged nouns that were masculine in their languages to be higher in potency than feminine ones, and the tested nouns belonged to opposite genders in the two languages. Subjects assigned subjectively a potency value for each noun, on a 7-point scale. B&S presented 24 pairs consisting of a noun (e.g., ‘spoon’) and a proper name (e.g., ‘Erica’) to 16 German and 25 Spanish native speakers during a learning phase. All nouns were given in English. The subjects’ memory of *the sex of the proper name* that had been associated with a noun was examined during the testing phase. As expected, subjects were better able to remember the correct sex (82% correct) when the sex (e.g., ‘female’) matched with the gender (e.g., ‘feminine’), than when this was not the case (74% correct). Since the nouns were chosen to have opposite genders in the two languages, subjects showed opposite memory biases. B&S concluded that ‘people’s ideas about the genders of objects are strongly influenced by the grammatical genders assigned to those objects in their native language.’

As with experiment 1, what is important is not the observation that there is an interference in memory retention between gender and sex, but the *explanation* for this phenomenon. B&S tacitly assume people make a direct connection between the concepts ‘masculine’ and ‘male’, and between ‘feminine’ and ‘female’.

This direct connection may be ‘traversed’ in the Spanish speaker’s mind when presented with the word ‘moon’ (in Spanish: ‘luna’, of feminine gender), so that they match the ‘femaleness’ of the moon with the femaleness implied by a name like ‘Karla’. A German speaker performing the same task (being presented with ‘moon’ – ‘Karla’) would experience inhibition between moon’s ‘maleness’ (in German: ‘Mond’, masculine), and Karla’s femaleness, resulting in slightly worse memory performance.

Plausible as this explanation might appear, it makes more sense in the mind of a native speaker of a natural gender language (such as English), where ‘male’ – ‘masculine’ and ‘female’ – ‘feminine’ nearly coincide conceptually. For a native speaker of a formal gender language this explanation seems to be simplistically projecting the natural-gender speaker’s view of the world onto everyone else. An alternative explanation is that the interference is caused by a much more indirect relation between noun and proper name than what B&S hypothesize. For example, the word ‘moon’ in a Spanish speaker’s mind evokes involuntarily, instantly, and subliminally, the Spanish word ‘luna’. This word is of feminine gender, and is related to the feminine ending ‘-a’, the pronoun ‘ella’, and so on. The proper name ‘Karla’ is also of feminine gender in the Spanish speaker’s mind (75% of all female names tested by B&S ended in ‘-a’, the marker of Spanish morphology for feminine nouns), and thus instantly and subliminally related to the same grammatical items (‘ella’, ‘feminine’, etc). We should note that I make no reference to ‘moon’s sex’ in this conceptual plan. In other words, there is a lot of overlap in linguistic connections between ‘moon’–‘luna’ and ‘Karla’ in the Spanish speaker’s mind.² No experimental setting can sever these linguistic connections, and allow us to test exclusively the connections ‘feminine’ – ‘female’ and ‘masculine’ – ‘male’. I do not claim that such direct connections do not exist in the mind of a formal gender language’s speaker. Such connections *do* exist. They may be learned in school, where the words for ‘masculine’ and ‘feminine’ are used as labels for categories of nouns the native speaker has already acquired at a very early stage; or they may be based on the small number of sex-related nouns. What I do claim is that experiments such as the one described by B&S (and Konishi) do not necessarily detect the direct influence of a supposed ‘sex of nouns’ on cognition in speakers of languages with formal gender, but instead the very intricate and indirect connections between gender and sex in such languages, which are of both a perceptual as well as a linguistic nature.

² This argument is weaker for German speakers, but then we are not given the difference in performance between German and Spanish subjects in B&S’s second experiment.

Evolution of Gender

What could the origin of grammatical gender be? B&S hint at possible common intuitions of people across languages, and attempt to quantify this assumption by examining the intuitions of speakers of English. I performed a similar comparison of such intuitions against Indo-European languages, and found that such intuitions do not show any particular correlation with the studied languages (Table 1). Moreover, it would be meaningful to talk about such a correlation *if languages agreed among themselves*. Otherwise, if we find a correlation between the intuitions of monolingual speakers of English and, say, Kurdish, we do not have any reason to assume there is anything other than chance involved. Looking back at the data in Table 1, we see that the only agreement that can be observed among languages is *between members of the same subfamily* (e.g., Portuguese–Spanish, etc.). The more phylogenetically distant the languages, the lower their correlation is (allowing for statistical errors). This hints at a possible answer to the gender-origin question.

That all Indo-European languages evolved from a common ancestor is indisputable. It is plausible to assume that this ancestor language employed a gender system, possibly one with a semantic basis. But what could have caused its modern descendants to assign genders such as masculine and feminine to inanimate objects? And how can a “pure” system (I mentioned Tamil as an example in the introduction) evolve into the modern chaos and disagreement?

The answer some authors have given to these questions is that the origin of gender is purely formal: some suffixes of sex-differentiable nouns acted as attractors, and created the genders in a purely formal, non-semantic way (Brugmann, 1899). This leaves open the question of what caused sex-differentiable nouns, rather than any other category, to become attractors. Another possible answer is that in some languages the initially semantic neuter gender was lost, and the void was filled by masculine and feminine genders being assigned to previously neuter nouns. Such a process can be observed today in Russian, where neuter nouns are only 13% of the total, and loanwords entering the language go primarily to the masculine gender, but also to the feminine (Corbett, 1991:317). This hypothesis does not take into account languages that retain the neuter gender, and still assign masculine and feminine genders to inanimate objects (German, Greek, etc.).

An alternative hypothesis is that masculine and feminine assignments to inanimate objects existed even in the original Indo-European ancestor. Although such assignments seem nonsensical today, they might have “made sense” in the remote past, at least among the few speakers of the ancestor language, based on animistic conceptions of the world. It could have appeared natural to a particular culture that, for example, a stone is of female sex. However, as the original language

evolved, ideas about the stone’s sex changed, too. Since there is no objective way to agree on something like the sex of a stone, the “opinions” among descendant languages evolved differently. What we observe today appears as a purely formal and arbitrary assignment, since the original “reasons” have been lost. One prediction of this hypothesis is that gender evolution in such languages should be traceable through a weak agreement between phylogenetically proximal languages. I believe the present work supports this implication, although further investigation of the hypothesis is clearly needed.

Acknowledgements

I would like to thank my advisors, Douglas Hofstadter, for bringing B&S’s paper to my attention and motivating my work; and Michael Gasser, for his valuable comments and suggestions. Also, Nathan Basik, for his careful proofreading of the text.

Appendix A: Words Examined

The 84 words in four categories are listed below. For the abbreviations used for the 14 languages see Table 1 (in text). The codes of gender values are as follows: -1 for masculine, 0 for neuter, 1 for feminine. Any intermediate values reflect the fact that more than one assignment was possible for a noun (e.g., 'sea' in German and Spanish), or more than one noun of differing gender corresponded to the same concept. Blanks indicate that I could not obtain the appropriate

gender (or the word is not native to the language). The last column (En) presents the average assignments of 20 American English monolinguals. Words marked with a star (*) were disambiguated for subjects who were asked to assign a gender as follows: table (furniture); chair (furniture); fork (utensil); bridge (over river); paper (a sheet of); bed (furniture); key (locking a door); watch (measuring time); star (on sky); gold (metal); power (of ideas, of wealth); revolution (of people).

Recovering Context After Interruption

Abstract

As information systems become more complex and present an increasingly rich amount of information to users, interruptions present an ever larger hurdle to operational efficiency. User interface technologies intended to support increased user-control of the transitions between computer-based tasks can help mitigate that obstacle. We present a three-pronged approach that combines dynamic interruption coordination support with context review mechanisms to aid user navigation through interruptions. These mechanisms are implemented within a spoken dialogue interface system for a radio-based human-software agent military logistics task.

Introduction

Modern information technologies continue to successfully deliver ever more powerful information products. This increase in power, however, can support the user in performing tasks quickly and accurately only if users can exploit this increased information flow for their own needs. People have a limited capacity for information management that directly affects the quality of their decision-making in stressful real-world tasks. If the ever-increasing information stream is not properly managed, these human capacities could become overloaded. The net result is that the adoption of a new information technology can actually cause an overall decrease in mission performance.

New, more powerful information technologies may increase the volume of important information delivered to decision-makers, but at the same time increase the frequency of interruptions of those decision-makers, degrading their information management capacity. The number of alerts that interrupt users affects how they manage their limited attentional cognitive resources. An interrupting alert causes users to switch from their current task to the new alert task. After completing the alert task, users must switch tasks again to resume what they had been doing prior to the interruption. The cognitive demands of these context switches increase the effective workload of users, which in turn increases the probability of mental mistakes.

For example, Foushee and Helmreich (1988) found that the disruptive effects of interruptions have

caused flight errors in commercial airline flights, sometimes resulting in fatal crashes. Human interruption is also a recognized problem in domains such as Navy command and control systems (Osga, 2000) and flightdeck or cockpit systems (Barnes, 1990; Adams and Pew, 1990; Adams et al., 1995).

The literature is rich with descriptions of the cognitive limitations people have relative to resuming tasks after being interrupted. Miyata and Norman (1986) give a general overview of the topic, discussing foregrounded and backgrounded activities and how interruptions are the standard way people switch between tasks in multitasking. Liu and Wickens (1988) discuss task interference and the effect of task type in human multitasking. McFarlane (2002) provides an in-depth review of the published relevant theory and proposes both a definition of human interruption and a taxonomy for classifying human interruptions.

Other studies investigate the causes of the disruptive nature of interruptions. McLeod and Mierop (1979) examine the effect of task similarity for manual tasks. Zijlstra and Roe (1999) found that the frequency of interruptions in an office environment affects the length of delay for people resuming the main task. Latorella (1998) found a modality interaction effect between how interruptions are presented (aurally or graphically) and the type of task that cockpit crew members perform (aural or graphical); different combinations of interface solution and task type resulted in different kinds of adverse effects on crew behavior. Linde and Goguen (1987) found that differences in how cockpit crews interact with each other affect their ability to successfully handle interruptions.

The objective of human alerting technology is to cancel the negative effects of human interruption and allow users to exploit the benefits of greater information volume for making better decisions. Human alerting mechanisms are being integrated within a broad range of commercial and military applications. These include announcement mechanisms for relatively less important systems like email, telephone, voicemail, internet instant messaging, chat rooms, automated help systems (like Microsoft's "Clippy"), computer-based tutor-

ing, and shopping agents. These applications also include many mission-critical systems including military command and control (C2), aircraft flightdeck control, power plant operations, spacecraft control centers, and real-time targeting sentinel-agent systems. McFarlane and Latorella (2002) present an in-depth discussion of the scope and importance of human interruption for HCI design.

Approach

There are three basic strategies for improving human performance on an interruption-laden multitask: (1) training (Hess and Detweiler, 1994); (2) selection of users (Joslyn and Hunt, 1998; Joslyn, 1995); and (3) user interface design. Due to the constraints of our real-world applications, we have focused our approach on the last option.

Our objective is to support efficient task recovery after interruption. It is useful to divide many user interface design approaches for human interruption into three phases. The pre-interruption phase prepares the user to transition from the main task to the interrupting task. The mid-interruption phase generally focuses on the user's transition to the interrupting task and includes the user's efforts and ability to maintain situational awareness of the main task while working on the interrupting task. The post-interruption phase sees the user return and reorient to the context of the original task that was interrupted.

Our approach has three parts, matching each of the three interruption phases.

Pre-interruption

Before the actual interruption takes place, the interface should give the user support for quick rehearsal of the current task before switching context to handle the interruption. Gillie and Broadbent (1989) noted that rehearsal may have potential for aiding human interruption in user interface design. Storch (1992) suggests that rehearsal may be useful in diminishing the negative effects of interruption after obtaining unexpected results in experiments unrelated to rehearsal. Detweiler et al. (1994) describes two experiments related to early warnings of interruptions that indicate that providing warnings is only marginally useful if the interruption task has a low memory load and is dissimilar to the main task while providing warnings can be extremely useful if the interruption task has a high memory load and is similar to the main task.

To allow the user to rehearse before interruption, some cue must precede or accompany the incoming alert. This cue helps to differentiate between the main task and interrupting task contexts and can take many forms, such as a visual flash, an audible beep, or a vibration. Because our particular applications involve a spoken dialogue interface, we have differentiated incoming alerts from the current task

by having the interface use a different voice. For example, the interface may use a female voice while participating in dialogue related to the user's current task, then switch to a male voice when introducing the interruption to the user. This cue gives the user the opportunity to register the alert, allowing the user to rehearse the context of the main task before continuing into the interruption.

Mid-interruption

When the interruption occurs, the interface should support user control of context switching and help the user maintain situational awareness of backgrounded tasks. This switch can take many forms. McFarlane (2002) conducted a theory-based experiment that compared four basic alternative solutions to the problem of how to coordinate human interruption in computer user interfaces. These four solutions are: (1) interrupt immediately and get it over with; (2) provide negotiation support so that the user controls the timing and exact context of switching between tasks; (3) provide intelligent mediation that brokers the onset of interruption tasks on behalf of the user; and (4) the use of scheduled interruption time cycles so that interruptions only occur during set times or contexts. Of these four solutions, negotiation was measurably the best approach for all kinds of user performance, except in cases where even small differences in the timeliness of handling interruption tasks are critical (either the current task is too important to allow distraction by the negotiation process, or the interrupting task is too important to wait for the negotiation to be completed).

Our approach involves the intelligent, automated selection of interruption strategy on a case-by-case basis. Our selection criteria is based on a dynamic automated assessment of the relative importance between the current task and the interrupting task. If the interrupting task is mission critical compared to the current task, the user is interrupted immediately. If the current task is critically important compared to the interrupting task, the alert is held until the user is finished with the current task (that is, it's scheduled for the next cognitive break). In all other cases, the interruption is negotiated.

To further aid the user in assessing relative task importance, we vary the default option in negotiation. That is, if the interrupting task appears to be slightly more important than the current task, the default option for the user is to accept the interruption. If the interrupting task is not deemed to be of higher importance, the default option for the user is to defer the interruption until the next cognitive break. Table 1 presents the full interruption strategy selection process for a three-valued priority system.

Interruption Task	Current Task		
	high	medium	low
high	Negotiated, default defer	Negotiated, default interrupt	Interrupt immediately
medium	Negotiated, default defer	Negotiated, default defer	Negotiated, default interrupt
low	Defer interruption until cognitive break	Negotiated, default defer	Negotiated, default defer

Table 1: Interruption Strategy Selection based on relative priority

Post-interruption

After the interruption is complete and the user transitions back to the original, interrupted task, the interface should provide recovery support to the user. That is, it should provide mechanisms to aid the user in recalling the context of the interrupted task, helping the user return more quickly to that previous task. Malin et al. (1991) state that user interfaces should be designed to reorient users to previously interrupted activities when they try to resume them. In their work, a simple log of relevant recent decisions is made easily available to the user for reference.

Our approach to context recovery involves providing the user commands that query the interface about aspects of the previous task. In a spoken dialogue system, this takes the form of meta-dialogue, with possible queries like "Where was I?" or "What was I last working on?" The user can also ask questions specific to the task, such as inquiring which supplies have been ordered so far in a requisition application.

Finally, the user can request a full progress review of the interrupted task. This provides a complete replay mechanism to the user, catching the user up to previous task context quickly and in detail. In a spoken dialogue system, this takes the form of requests for a summary of the task progress to-date.

Implementation

As a testbed for our approach to intelligent alerting and interruption management, we applied our techniques to a spoken dialogue interface. We have implemented a number of speech applications following the Listen, Communicate, Show (LCS) paradigm (Daniels, 2000). LCS systems integrate mixed-initiative spoken dialogue interaction with mobile intelligent agents to provide a natural, robust interface to information systems.

In most domains, users can use LCS to command agents to persistently monitor information sources for specific information events. When these events occur, the agents inform the LCS interface, which calls and alerts the user. If the user is currently

engaged in another task, this agent-initiated conversation can result in an interruption.

The spoken dialogue portion of an LCS system is built upon the Galaxy architecture developed at MIT (Seneff et al., 1999). Galaxy supports distributed, plug-and-play systems in which specialized servers are coordinated through a centralized communication hub. LCS systems contain servers specialized for speech and natural language processing, a dialogue manager to direct the system's side of the conversation with the user, and an agent server for communicating and coordinating with the agent system.

Originally, when LCS monitor agents would notify the user, they would communicate to the dialogue manager directly through the agent server. The dialogue manager, which contained limited control mechanisms for interruption, would interject the interrupting alert at the next available moment in the dialogue. This would ensure that the user would not be interrupted mid-utterance, but does not take into account the effects of interruption on the user's cognitive state.

To integrate our new interruption techniques, we added several new servers to the LCS architecture (see Figure 1 for illustration). The priority server ascertains the relative priorities of the current and interrupting tasks. The dialogue manager keeps the priority server informed of the task in which the user is engaged, while the agent server communicates the priority of incoming alerts.

The interruption server selects the interruption strategy most appropriate for the relative priority determined by the priority server. Once the interruption strategy is determined, the interruption server supervises as the system enacts the strategy. If the interruption is deferred, the interruption server tracks it to make sure that the alert is eventually delivered.

Because negotiated interruptions require interaction about the interruption (rather than about the interrupting task itself), we implemented a dialogue manager to drive this interaction in a domain-independent manner. The negotiation manager controls the system's part of the negotiation process and

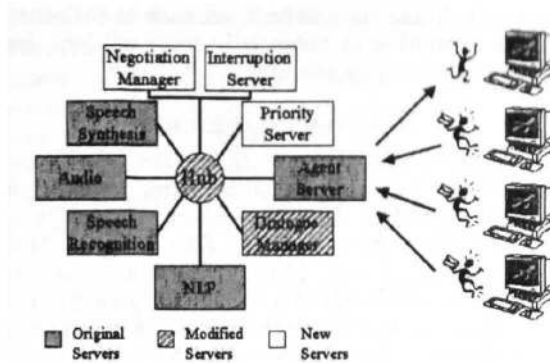

Figure 1: The ability to task multiple agents to perform persistent tasks (such as monitoring information systems) is a strength of LCS systems. However, since multiple agents may return results at the same time, advanced methods for handling interruptions were required. Some enhancements to the standard LCS architecture were required to implement these new interruption mechanisms.

coordinates with domain-specific dialogue managers to ensure that the system speaks to the user in a reasonable, focused manner.

In addition to constructing the new servers, we made several enhancements to the already existing LCS infrastructure. We implemented the meta-dialogue for post-interruption context recovery by adding logic for meta-dialogue control to the domain-specific dialogue managers. We also added an intuitive pre-interruption cue, programming the hub to have the system use voices for interruptions that are different from the voice used for the interrupted task.

Application

We applied the new interruption techniques to an LCS domain that supports Marines in managing requests for supplies using regular military radio protocols. This application was originally developed as part of the Small Unit Logistics (SUL) Advanced Concept Technology Demonstration (ACTD) program. The spoken language interface assists a Marine user in placing, modifying, deleting, or checking the status of a supply request. The SUL system also supports the creation of monitor agents to track requests and notify the user when either the status of the request changes or if the agent observes that the request hasn't been given attention over a set period of time.

In its original implementation, the SUL system would accommodate these returning notification activities by waiting until a break in the current conversation before providing any notification results to the Marine, regardless of the priority of either the no-

Figure 2: Example opening utterances for each interruption strategy. In all cases, a voice different from the one the user had been listening to was used for the alert. Note that when an interruption occurs, the user is explicitly informed of the new task's priority to support the user's decision to switch tasks.

tification activity or the current task. By allowing the SUL system to break into an ongoing conversation with important news, we can create a spoken dialogue interface that more realistically emulates radio protocols. However, this feature brings with it all the challenges associated with interruptions that have been discussed throughout this paper.

To support interruption strategy selection, we established a priority comparison scheme based on the priority field of each logistics request. For a SUL request, there are three priorities: routine, immediate, and urgent. We mapped these priorities to the low, medium, and high priority scheme described earlier in Table 1. We used the interruption strategy selection method described in this paper to govern delivery of agent alerts. Figure 2 shows examples of how interruptions would be presented to the user for each strategy.

To support post-interruption context review, we implemented two sets of meta-commands, relying on radio protocol to guide us. In the first case, the system repeats just its most recently stated utterance from the prior conversation. For the SUL domain, the proword (that is, a military procedure word) "Read back" is used. In the second case, the system reiterates all information it has been given about the current task. Figure 3 shows an example in which the user has requested more than just the prior system utterance. For this, the proword "Read back my request" is used.

In addition, we implemented dialogue that allows the Marine user to examine specific parts of a supply request by querying the interface specifically about

that part. For example, the user might ask, "Who is the point of contact for this request?" or "How many grenades did I order?" This provides the user complete control in returning to the context of the interrupted supply request. Similar dialogue supports the user in orienting quickly to interrupting alerts about other supply requests as well.

The SUL spoken dialogue system, with alerting enhancements, has been demonstrated successfully multiple times in operational settings. The enhanced LCS alerting infrastructure is being used as the basis for several more applications that will be field tested in the near term.

Future Work

We are working toward several enhancements of the current LCS interruption mechanisms. In each case, the enhancements build upon a core capability present in the current system.

Our current use of overall task priority to select interruption strategy assumes that a coarse-grained decision is sufficient. A more-informed decision would result from a finer-grained knowledge of where the user is in the current task. For example, in the SUL domain, the system is programmed with knowledge of the information that is necessary to fully complete a supply request. With its programmed knowledge of the request process, the system should be able to ascertain how close the user is to the beginning or end of completing the task, or if the user is in the middle of clarifying a particular step in the task process.

We are also investigating adding multiple modalities, where possible, as a method to further differentiate interrupting tasks from the current task, taking advantage of modality effects like those described in (Latorella, 1998). While our use of different voices helps, the use of another modality to cue interruption may prove more helpful to the user in mitigating cognitive disruption. This approach will be implemented and tested in the field.

In addition, we plan to add finer control of context review. Currently, our system provides for review of prior context in one of two forms: either the most recent system utterance or the entire set of known information items that the system has. While this is quite useful, with long, complex tasks, an intermediate level of detail might be preferred. We plan to construct and test dialogue methods for giving the user that finer control.

Conclusions

The disruptive effects of human interruption by information systems is a serious concern, particularly in high stress situations such as military operations. There are technical solutions available at all points during the interruption process to help mitigate this problem. By alleviating this cognitive disruption,

we can help the user move from task to task more quickly, resulting in potentially more efficient, less error-prone work by the user.

Four Problems with Extracting Human Semantics from Large Text Corpora

Robert M. French and Christophe Labiouse

Abstract

We present four problems that will have to be overcome by text co-occurrence programs in order for them to be able to capture human-like semantics. These problems are: the intrinsic deformability of semantic space, the inability to detect co-occurrences of (esp. distal) abstract structures, their lack of essential world knowledge, which humans acquire through learning or direct experience with the world and their assumption of the atomic nature of words. By looking at a number of very simple questions, based in part on how humans do analogy-making, we show just how far one of the best of these programs is from being able to capture real semantics.

Introduction

"You shall know a word," wrote J. R. Firth in 1957, "by the company it keeps." This idea, in one form or another, underlies the statistical study of the co-occurrence of lexical items in large text corpora. This burgeoning field of research has been made possible to a large extent by the ready availability of vast databases of text that can be automatically scanned by computer. While we certainly do not dispute the value of the statistical study of large text corpora, we take issue with the claim that lexical co-occurrence alone can capture real-world semantics. We focus on four main problems with co-occurrence analysis programs:

- they do not take into account the intrinsic deformability of semantic space due to context-dependence;
- they cannot detect co-occurrences of abstract structures, especially when they are highly distal;
- they lack of essential world knowledge, which humans acquire through learning or direct experience with the world;
- they assume that words are "atomic" entities.

These issues are ones that will have to be effectively dealt with by text analysis techniques in order for them to capture even elementary human semantics. These points will be examined in the context of human analogy-making.

The remainder of this paper is organized as follows. We begin by discussing the relationship between analogy-making and concept meaning and show why current co-occurrence programs would have so much difficulty with this broader view of concept meaning. We then consider one of the best recent co-occurrence programs, PMI-IR (Turney, 2001a) and show just how far this program is from being able to plausibly respond (i.e., in a human-like manner) to even the simplest possible analogies.

The intrinsic deformability of semantic space

We will take issue with one of the main principles underlying LSA (Landauer and Dumais, 1997), HAL (Lund & Burgess, 1996) and other programs based on lexical analysis of large corpora – namely, that "The meaning of a word can be thought of as a location in semantic space and the dimensionality of that space and the location of any word within it can be recovered from estimates of the distance between word pairs." (Fletcher & Linzie, 1998). The implication is that words have stable, fixed locations in semantic space. While this is obviously not entirely false, this principle overlooks the fact that these locations in semantic space are *highly context dependent*. They not only can, but *must* be able to move considerably in semantic space depending on the context in which they are to be used.

Consider a very simple example. A "claw hammer" would, under most circumstances, be close in semantic space to terms like "ball-peen hammer," "hit," "pound," "nail," "saw" and, even, "club." However, if, while nailing a floor, you suddenly have a back itch, the "claw" part of the hammer will likely become much more salient as a back-scratcher, rather than a nail-remover. Your realization that you can use the hammer as a back-scratcher temporarily moves the object in semantic space much closer to "back-scratcher," "itch," etc., than when it is perceived only as an object with which one can drive in nails. This "relocation" of the meaning of a word/concept in semantic space based on context is at the very heart of analogy-making, of perceiving one object as an instance of another class of objects (Chalmers, *et al*, 1992; Hofstadter, 1995). It is therefore essential to any algorithm that claims to be able to automatically extract word meaning from very large text corpora. And it is precisely this ability to relocate in semantic space in a context-dependent manner that is currently beyond the reach of all co-occurrence techniques.

In short, while co-occurrence techniques may plausibly situate a word in semantic space with respect to its *average* usage, this is not sufficient to capture the context-dependent shifts in word meaning required to understand even the simplest analogies on which so much of our cognition is based. For this we need to somehow extract, at the very least, abstract relational information concerning the word.

Detection of (distal) abstract structures

Acquiring the semantics of a particular word allows us to rate the quality of associations between that word and other words. To plausibly claim that a program has acquired, or even partially acquired, the semantics of a word means that it should give word-association ratings that are at least approximately similar to those given by humans (French, 1990). We will use this rating technique to judge the performance of text co-occurrence programs.

There are (at least) two different bases for these associations, even if this distinction is not always easy to characterize (Chalmers, French, & Hofstadter, 1992). To say, "John is a real beanstalk," refers to largely "surface" attributes of John and beanstalks — namely, they are both tall and thin. On the other hand, when we say "John is a real wolf with the ladies," we don't mean John grows long gray hair around women and bites them, but rather that his *relation* with women is socially predatory, analogous to a wolf's relation of physical predation with its prey. The first analogy is largely *attributional*, based essentially on common surface features (in this case, the attributes "tall" and "thin") of John and beanstalks, whereas the latter analogy is primarily *relational*, based on a mapping between John's behavioral interactions with women and wolves behavioral interactions with prey. The first kind of association can be captured by co-occurrence techniques, whereas the latter — the basis of virtually all deep analogy-making (Gentner, 1983) — is still well beyond the reach of these techniques.

Incorporating semantic information

An equally important difficulty involves the unavailability to these programs' of crucial semantic information that cannot be acquired merely by examining word co-occurrences. In two of the examples below this lack of crucial contextual knowledge — that fathers are always male in one example, and the fact that there is an undeclared war going on between the Israelis and the Palestinians in the other — causes the particular text co-occurrence analysis program under consideration to fail completely in responding to the simplest questions involving word meaning. Humans acquire this information through direct experience with the world or through explicit learning, whereas these programs currently have no way of acquiring it. The point is that, when making judgments about word meaning, people — unlike co-occurrence programs — make use of a wealth of relational and semantic information that is unrelated to word co-occurrence.

Words are not atomic entities

Consider an example of a "subcognitive" question from French (1988, 1990) involving the rating of a neologism. "On a scale of 1 (awful) to 10 (excellent) please rate:

- *Flugly* as the name of glamorous Hollywood actress,

- *Flugly* as the name of an accountant in a W. C. Fields movie."

Humans, of course, can do these two ratings without difficulty: *Flugly* is a decidedly lousy name for a glamorous Hollywood actress and a fine name for an accountant in a W. C. Fields movie or a teddy bear. But how do we "know" this, since you have never seen the word *Flugly* before? You know, at least in part, that *Flugly* doesn't work for the name of a glamorous actress because of its *component parts* (French, 1990). In particular, it contains an unpleasing-to-the-ear guttural "g," to say nothing of the syllable "ug" or the entire word "ugly." Similarly, we rate it as a good name for an accountant in a W. C. Fields' movie because, in our mind's ear, we hear him pronouncing the name as "Flugleeee." This requires phonetic information acquired by having heard W. C. Fields' unique manner of speaking (or having heard others imitating this manner) and by the fact that various components of *Flugly*, namely, "ly," can be transformed into a drawling "leeee."

The point is that words contain parts that contain crucial information that contributes to the overall meaning of the word. Co-occurrence programs are currently insensitive to this information. And it is not clear that by extending their analyses to the letter or syllable level that i) there would not be a problem of combinatorial explosion and ii) that this would be an appropriate way to acquire this information.

PMI-IR

In the examples that follow, we will consider the performance of one recent program, PMI-IR (Turney, 2001a, b), that, according to its author, outperforms all other current programs on the most widely used benchmark for programs that attempt to extract word meaning from large text corpora. This benchmark is their performance on the standard synonym selection tasks that are part of the Test Of English as a Foreign Language (TOEFL) and the test of English as a Second Language (ESL).

The co-occurrence technique used by PMI-IR is one of a family of "Pointwise Mutual Information" (PMI) techniques developed by Church & Hanks (1989) and Church *et al.* (1991). In order to calculate the conditional probability scores on which it bases its choice of the correct synonym, the program queries 350 million pages of English text indexed by the AltaVista search engine. The most sophisticated version of PMI-IR is able to make use of local (proximal) context in order to correctly answer questions such as, "Every year in the early spring farmers [tap] maple syrup from their trees (drain; boil; knock; rap)." As Peter Turney, the author of PMI-IR, points out, "the problem word *tap*, out of context, might seem to best match the choice words *knock* or *rap*, but the context *maple syrup* makes *drain* a better match for *tap*" (Turney, 2001b). The program factors in the context provided by "maple syrup" to correctly answer this question.

The program does, indeed, perform impressively on the synonym recognition task. According to Turney, the

program produced the following results on the standard TOEFL and ESL synonym recognition task:

"The task of synonym recognition is, given a problem word and a set of alternative words, choose the member from the set of alternative words that is most similar in meaning to the problem word. PMI-IR has been evaluated using 80 synonym recognition questions from the Test of English as a Foreign Language (TOEFL) and 50 synonym recognition questions from a collection of tests for students of English as a Second Language (ESL). On both tests, PMI-IR scores 74% . . . For comparison, the average score on the 80 TOEFL questions, for a large sample of applicants to US colleges from non-English speaking countries, was 64.5% (Landauer and Dumais, 1997). . . . Latent Semantic Analysis (LSA), another statistical technique, scores 64.4% on the 80 TOEFL questions (Landauer and Dumais, 1997)."

Three examples

In what follows we use a word-rating technique from French (1988, 1990) and similar to standard similarity judgment techniques used to study how word meanings are represented (see, for example, Rips, Shoben, & Smith, 1973). The key idea is that these simple questions require non-local context for their answers (French & Labiouse, 2001).

Rating lawyers

Our first example involves the rating of *lawyers* as various other entities.

"Rate on a scale of 1 (terrible) to 10 (excellent) rate *lawyers* as: horses, fish, telephones, stones, sharks, cats, flies, birds, slimeballs, kangaroos, robins, dogs, and bastards."

We applied the PMI-IR search technique described in Turney (2001b) using the Alta-Vista search engine and found that it gave the *lowest* (i.e., poorest) ratings to "Lawyers as slimeballs" (1.06) and "Lawyers as bastards" (1.15), the latter being roughly equivalent PMI-IR's rating of "Lawyers as kangaroos" (1.17)! We then asked a group of 26 undergraduates at Willamette University (Oregon) to also do these ratings. These results (Figure 1) are much more in line with one might expect for humans with a clear understanding of the semantics of the word "lawyer" — namely, lawyers are judged (fairly or unfairly) to be most like slimeballs, bastards, dogs and sharks, and least like telephones, kangaroos, and birds. PMI-IR, on the other hand, judges lawyers to be most like computers, cats, and telephones and least like slimeballs, bastards, kangaroos and robins. Lawyers as sharks or fish are judged to be equally bad. A comparison of human vs. PMI-IR results can be seen in Figure 1. In short, it is amply clear that even for this straightforward question about lawyers, the human semantics of "lawyer" does not even vaguely resemble the semantics extracted by PMI-IR.

Figure 1. A comparison of PMI-IR and human data. The two profiles are clearly very different.

We also found that PMI-IR gave an extremely high rating to "Lawyers as children," higher, in fact, than any of the choices tested in Figure 1. Clearly, something is wrong here: first, lawyers cannot even *be* children (something which PMI-IR has no way of knowing) and, even metaphorically, it just doesn't seem right to us.

Rating the plausibility of Jewish/Palestinian ministers' names

Next we used PMI-IR to judge how good various first names would be for an Israeli or a Palestinian minister. We chose ten traditional Jewish names (Uri, Ariel, Moshe, Yitzhak, Yehudi, David, Samuel, Benjamin, Shimon, and Zeev) and nine traditional Arab names (Saddam, Usama, Ahmed, Mohammed, Salah, Amin, Khalil, Ashrawi, and Yasser). We asked two separate questions, each processed independently by the program. The first was "How good is X [one of the names, e.g., *Ahmed*] as the name of an Israeli minister?" All nineteen names were rated for this question. Then a second question was asked: "How good is X [again, one of the 19 names] as the name of a Palestinian minister?" All 19 names were rated for this second question. We then compared the ratings for each name for the two questions to determine their degree of correlation.

Once again, PMI-IR fails rather spectacularly: for example, it considers *Yasser* to be almost as good a first name for an Israeli minister as for a Palestinian minister! Similarly, *Ariel* is judged to be the best name, out of all ten Jewish names and all nine Arab names, for either an Israeli minister or a Palestinian minister. The results for the other names are shown in Figure 2.

Why does the program rate *Yasser* as a highly probable name for an Israeli minister and *Ariel* as highly probable for a Palestinian minister? The reason is simple: Because the program is concerned *only* with the co-occurrence of words, in this case the words *Yasser*, *Ariel*, *Israeli*, *Palestinian* and *minister*. The fact that Israel and Palestine are currently waging an undeclared war is known to PMI-IR only through higher than normal co-occurrences of war-related words and words like *Israel*, *Palestine*, *intifada*, etc. It knows nothing about wars, about their causes and effects, about their effects on societies and individuals in those societies, about hatred, about destruction, about refugees, about Israel, about Palestine, etc. *ad infinitum*. It knows only that sometimes these words co-occur with higher

frequency than others. The complete absence in PMI-IR of this deep relational structure in which the words that it encounters (and concepts these words represent) are embedded is precisely why PMI-IR fails to convincingly answer even the simplest questions that require deeper relational structure and knowledge to be answered plausibly.

So, to return to our example, in the context of the current crisis in the Middle East and of cultural specificities of first-names, good names for Palestinian ministers should be perceived as bad names for Israeli ministers and vice-versa. PMI-IR is, as we have said, unaware of the cultural context surrounding these questions. Specifically, PMI-IR is ignorant of the obvious (to us) cultural fact that some first names are typically Jewish while others are typically Arab and the relation of that cultural fact to the currently perceived inappropriateness of Palestinian ministers with Jewish names and vice-versa. So, according to PMI-IR, the appropriateness of a name for a Palestinian minister correlates almost perfectly (+0.98) with the appropriateness of the same name for an Israeli minister (See Figure 2).

Figure 2. For two separate questions: "How good is X as the name of an Israeli minister?" and "How good is X as the name of a Palestinian minister?" PMI-IR produces an almost a perfect correlation between the appropriateness of a given name as either that of an Israeli or a Palestinian minister.

Rating names of mothers and fathers

Finally, we decided to pick an example, simple in the extreme and far removed from politics and current events, that relied on a very specific piece of contextual information that would be available to all humans but not to a word co-occurrence analysis. We compared PMI-IR's answers to the following two questions: "How good is X [a first name] as the name of a father?" and "How good is X [the same first name as in the first question] as the name of a mother?" For each question we asked PMI-IR to rate ten very common men's names (John, William, Stuart, Peter, Robert, Jack, Gary, Steve, Albert, and Michael) and ten very common women's names (Barbara, Mary, Patricia, Linda, Susan, Jennifer, Karen, Nancy, Elizabeth, and Dorothy).

When judging the appropriateness of a particular name as the name of a father (or mother), humans partly rely on a simple fact that the program does not have — namely, that fathers are invariably men, while mothers are invariably women. Consequently, humans will necessarily rate women's names lower than men's

names for the question: "How good is X as the name of a father?" Not so PMI-IR. The program concludes that "John" is the best name out of all twenty names for a father *and for a mother*. It rates "Mary" as being a very good name for a father or for a mother. Ditto for the name "William." As in the above example, the appropriateness of a particular name for a father correlates essentially perfectly (+0.99) with the appropriateness of that same name for a mother! (Figure 3)

Once again, the program fails because extracting co-occurrences of words in a large corpus of text is simply not good enough to answer questions that require abstract contextual knowledge or experience. Again, the problem is that PMI-IR has neither abstract rules nor world experience that it can rely on. And since, in any text where the word "father" occurs, the word "mother" will generally not be far away, PMI-IR fails completely on this simple rating task.

Figure 3. Two questions were asked: "How good is X as the name of a father?" and "How good is X as the name of a mother?" Lacking all context about what "fathers" and "mothers" actually are, PMI-IR produces an almost a perfect correlation between the appropriateness of the names, male or female, for a father or for a mother!

Why PMI-IR works so well on the synonym selection task

Given PMI-IR's poor performance on the simple examples above, how could it be so good in the synonym selection task, a task that would seem to require a relatively sophisticated semantic understanding of words in order to be done successfully? In what follows we will briefly examine why this program, and other similar programs, most notably LSA, are able to perform so well on this task, in spite of their inability to do the examples above.

The author of PMI-IR claims that his program can do better on the TOEFL and ESL synonym tests than any other current computer program (Turney, 2001a,b). This is believable and reasonable. Turney illustrates PMI-IR's performance on the synonym-finding task with the word *levy* (as in "to levy taxes"). Four choices are proposed — *imposed*, *believed*, *requested*, *correlated* — and the program chooses one of them as the best synonym based on how often that word is close to "levy" in many Web pages. The reason for PMI-IR's success does, indeed, reflect the semantics of the word under consideration, but is tied most directly to the stylistic reasons for which we use synonyms — viz., so

as not to repeat the same word too often in a given text or, especially, in the same paragraph. This purely *stylistic* constraint imposes the proximity of synonyms, which is detected by PMI-IR.

Assume you are writing an article to be put on a Web page about some *blunder* that occurred. In describing this blunder, you are aware that it is bad style to repeat the word *blunder* over and over again in your text, so you resort to synonyms, such as *failure*, *mishap*, *mistake*, *slip*, *bungle*, *mess*, and so on. This obviously produces co-occurrences of *blunder* and *mistake*, of *blunder* and *slip*, etc., and this is precisely what PMI-IR detects. A *blunder* IS (to a first approximation) a *mistake*, which IS a *slip*, etc. These words all have approximately the same dictionary definitions. In other words, the features that describe them are largely identical. This is what we called above *attributional similarity*. The point is that we can expect attributionally similar words, if only for stylistic reasons, to occur close to one another in a text. Hence, PMI-IR's excellent performance on this task.

This technique can, indeed, incorporate proximal context, as in the example of the word *tap* in the context of "maple syrup." But most analogical association involves abstract context derived from examples that, if they exist at all in the text corpus, may well be separated by millions of pages from the word under consideration. It is an open question in the field of computational analogy-making as to how this abstract relational structure might be stored and indexed fluidly enough to be accessible for later retrieval in a wide variety of contexts (see Chalmers, French, & Hofstadter, 1992, for a detailed discussion of this issue), but one thing is clear: it is *not* accessible to programs that rely only on local word co-occurrence to produce their semantics.

And, to be fair, this is one way in which humans learn attributionally similar words/concepts. But there is much more to "semantic similarity" than surface similarity.

To reiterate, *relationally* (or *metaphorically*) similar words require a great deal more than the detection of attributional similarity and physically proximal context. Consider rating a *banana split* as *medicine* (French, 1988, 1990). The number of times that these two items will occur together in any text anywhere is now, and will forever be, infinitesimally small compared to the other associations involving banana splits or medicine. For programs that extract semantics only from text corpora this poses a serious problem, referred to as the problem of data sparseness (Dagan et al., 1994). But the problem is unavoidable. *Of course* the number of Web pages containing the terms "banana split" and "medicine" will be vanishing small because is it not a common association at all, but it remains a perfectly valid, readily understandable one that we can judge without difficulty because we understand it *in relation to our experience with the world*, i.e., to facts like the doctor bringing us a bowl of ice-cream after we have had our tonsils out, with our mother taking us for a sundae to pick up our spirits when our junior high

school safety poster was eliminated from the city competition, etc.

In other words, describing one word in terms of another usually involves much more than the above kind of "blunder-mistake-mishap-slip" synonym searching. It involves mentally placing the both words in a variety of *relational* as well as attributional contexts (that can shift fluidly) and converging on a context that fits both words (for detailed discussions of this see: Chalmers, French, & Hofstadter, 1992; Hofstadter, 1995; etc.) If both words fit that context very well, then we give the association a high rating. The more difficult it is to converge on an appropriate context for both words, the lower the rating.

PMI-IR, however, is incapable of extracting these all-important relational and contextual characteristics of situations. Specifically, for questions of the form, "Rate X as a Y," the program is incapable of grasping the relational structure in which each of the words is embedded and then of mapping those two structures onto one another in order to determine the relational similarity of the words.

Conclusions

While we acknowledge the impressive performance on certain lexical tasks of programs that employ co-occurrence analyses on large text corpora, our contention is that these programs lack the capabilities necessary to acquire real (i.e., human) semantics. This paper must not be read as a criticism of these methods per se, but rather as an incentive for researchers to develop new techniques that can incorporate more of the mechanisms by which we humans acquire semantics. These requirements go well beyond the often-cited problems of the lack of syntactic knowledge (Perfetti, 1998) and conceptual disambiguation (Landauer & Dumas, 1997). We have pointed to four problem areas for these programs, areas in which we believe future research should be focused. These areas are i) the ability to cope with the context-dependent deformability of semantic space, ii) the detection of co-occurrences of abstract structures, especially similar, but distal, abstract structures, iii) the means of providing the programs with essential world knowledge, and iv) the elimination of the assumption of words as "atomic" entities. In other words, we maintain that to know a word in a manner even approximately equivalent to how we humans know it, requires far more than merely knowing the "company it keeps."

In short, while the area of text analysis of large corpora is a fascinating and promising one, we believe that in order for real, human semantics to emerge from these techniques, the problems raised in this paper will have to be squarely confronted and overcome.

Abstract

At the earliest ages of development, perceptual maturation is generally considered as a functional constraint to recognize or categorize the stimuli of the environment. However, using a computer simulation of retinal development using Gabor wavelets to simulate the output of the V1 complex cells (Jones & Palmer, 1987), we showed that reducing the range of the spatial frequencies from the retinal map to V1 decreases the variance distribution within a category. The consequence of this is to decrease the difference between two exemplars of the *same* category, but to increase the difference between exemplars from two *different* categories. These results show that reduced perceptual acuity produces an advantage for differentiating basic-level categories. Finally, we show that the present simulations using Gabor-filtered input instead of feature-based input coding provide a pattern of statistical data convergent with previously published results in infant categorization (e.g., Mareschal & French, 1997; Mareschal et al., 2000; French et al., 2001).

Background

This paper builds on earlier work by Quinn, Eimas, and Rosenkrantz (1993), Mareschal and French (1997), Mareschal, French, and Quinn (2000) and French, Mermillod, Quinn, and Mareschal (2001). Quinn et al. (1993) reported the following categorization asymmetry. Infants familiarized with a number of exemplars of cats show significantly increased interest when subsequently tested on an exemplar of a novel dog compared to a novel cat. However, if the infants are first familiarized with images of dogs and then tested on a novel dog and a novel cat, there is no significant difference in interest between the two test stimuli. Mareschal and French (1997) and Mareschal et al. (2000) attributed this to the greater variance of the "dog" stimuli set compared to the "cat" stimuli set, the interpretation being that the Dog category largely subsumed the Cat category. Thus, an infant familiarized on the less variable category, Cat, would, in general, view an exemplar of

a dog as a novel stimulus, whereas an infant familiarized on the more variable category, Dog, would tend to perceive a cat exemplar as simply belonging to the already-familiar Dog category. This, we claimed, explained the asymmetric levels of attention that Quinn et al. (1993) had observed. To further test this hypothesis, French et al. (2001) artificially reversed the inclusion relationship by carefully selecting breeds of dogs that were relatively similar (i.e., low variance) and highly variable breeds of cats. The connectionist computer model predicted, and the experimental results with infants subsequently confirmed (French et al., 2001), a reversal in the categorization asymmetry observed by Quinn et al. (1993).

However, one outstanding question remained. Even though, intuitively, the variability of the Cat category appears to be less than that of the Dog category, how could one be *sure* of this in any quantifiable way? Mareschal and French (1997) and Mareschal et al. (2000) handled this as follows. They originally selected ten features common to both cats and dogs (head length, head width, eye separation, ear separation, ear length, nose length, nose width, leg length, vertical extent, and horizontal extent) and measured the values associated with these features for each of the photos of the 18 Cat exemplars and 18 Dog exemplars used in their experiments. Even though this choice of features was based on experimental data where infants typically look at the head and face region of the stimulus when they observe an animal (Quinn & Eimas, 1996; Spencer, Quinn, Johnson, & Karmiloff-Smith, 1997), how could we be sure that the set of perceptual features that we had chosen corresponded to those features to which the infants were actually attending? Further, the claim was that at 3-4 months of age infants were not making use of previously acquired perceptual information (i.e., prior categorical knowledge of dogs or cats or, for that matter, ears, noses, legs, etc.); rather, they were simply relying on statistical pattern recognition. Under these circumstances, using a set of measurements of specific high-level perceptual

features to characterize the input seemed, if not

Figure 1: Transformation of the original image into a spatial-frequency map

Figure 2. Once we have the map of spatial frequencies, we "cover" this map with spatial-frequency ovals along various orientations of the image. (Each of the ovals are normalized to have approximately the same energy.)

necessarily incorrect, at least somewhat inappropriate.

We therefore decided to attempt to examine this problem in a more neurobiologically plausible manner, one which sidestepped the difficulties inherent in selecting and measuring various perceptual features of the cat and dog stimuli. The dog/cat stimuli used in the simulations reported in this paper were those used in French et al. (2001), all of which had been normalized to have approximately the same size.

Organization of the present paper

We will attempt to answer two questions in the present paper.

The first is: Can we avoid the use of explicit feature coding in our autoencoder model of infant categorization and replace this coding with Gabor-filtered input known to have a neurophysiological counterpart in the infant visual system? We will show that this can, indeed, be done successfully.

The second issue that we will address starts from the well-known fact that the 34 month old infant visual system is not sensitive to high spatial frequency information (Banks & Salapatek, 1981; Dobson & Teller, 1978). However, instead of this being a disadvantage for the infant, we will show that, somewhat counter-intuitively, this low visual acuity is

actually an *advantage* in learning basic-level categories. The claim is that high spatial frequency information in the input signal produces an "information overload" in the infant cognitive system, adding information that is not necessary for correct categorization but that must, nonetheless, still be processed. In other words, when the infant is attempting to learn basic-level categories, high spatial frequency information in the input is very much like noise (Turkewitz & Kenny, 1982; Turkewitz & Kenny, 1985) and, as such, the less there is, the better.

Spatial frequency maps

It is well known that different columns in V1 are sensitive to different ranges of spatial frequencies (De Valois & De Valois, 1988; Tootell, Silverman, & De Valois, 1981). A scene reconstructed from only low spatial frequency information (i.e., with fine details blurred out) appears to us to be blurry. On the other hand, an image composed of high spatial frequencies would show *only* the fine details and would have no global perspective (rather like seeing many individual trees, but having no sense of the global entity, a forest). In any case, in order to have an optimal perception of a scene, we need the entire range of spatial frequencies. Therefore, by means of a 2D

Fourier transform, we first decomposed each of the images in the stimulus set into its component spatial frequencies and plotted them on a spatial frequency map (see Figure 1).

We then covered the frequency diagram with a "flower-petal" arrangement of 26 oval spatial frequency areas ("filters") corresponding to various orientations emanating from the center of the spatial-frequency diagram (Figure 2). Gabor functions were used to simulate the 2D spatial and spectral structure of simple cells in visual primary cortex. (Jones & Palmer, 1987; Jones, Stepnowski, & Palmer, 1987). The smaller petals near the center of the map encompass the low frequencies, while the larger ovals further from the center group together high spatial frequencies. For each of these 26 filters, we calculate an "energy" value based on the local energy spectra, thereby simulating the activity of V1 complex cells (Sakai & Tanaka, 1999). This value determines the importance of that particular filter. If there are many spatial-frequency points that fall in a particular oval, it is given a high energy value; few points in a particular oval mean a low energy value.

Recall that in prior experiments and simulations (Mareschal et al., 2000; French et al., 2001), the dog/cat stimuli were characterized by a vector of ten values, with each value corresponding to a particular "high-level" feature. Now, instead of using ten features, we characterize each of the images by a vector of 26 values, each of which corresponds to the weighting of a group of spatial frequencies along various orientations of the image.

Visual acuity in infants

We know that the visual acuity in infants is not the same as that of adults (Banks & Salapatek, 1981; Dobson & Teller, 1978). In particular, infants do not perceive high-spatial frequencies (i.e., fine details), or perceive them only poorly. Certain authors (Turkewitz & Kenny, 1982; Turkewitz & Kenny, 1985) have claimed that, rather than being a problem, this reduced visual acuity may actually improve perceptual efficiency by eliminating the "information overload" caused by too many extraneous fine details likely to overwhelm their cognitive system. An implication is that basic-level category learning may be facilitated by reduced visual acuity.

In both of the simulations below we removed most of the high spatial frequencies from the input given to the autoencoder network that was used in Mareschal and French (1997), Mareschal et al. (2000), and French et al. (2001). This was done by weighting the contribution of each of the spatial frequencies according to a normal distribution (with the low spatial frequencies at the center) and cutting off all spatial frequencies above 7.1 cycles/degree. The spatial frequencies are Gaussian-filtered in such a way that spatial frequencies above 3-4 cycles/degree contribute very little to the input vector associated

with each image; the cut-off of 7.1 cycles/degree completely removes the highest spatial frequencies.

Overview of the simulations

The 26-16-26 autoencoder network used in the two simulations presented in this paper is based on a simple encode-compare-adjust principle (Sokolov, 1963; Charlesworth, 1969; Cohen, 1973): When an infant sees a perceptual stimulus, this stimulus is encoded as an internal representation, which is continually compared to the external stimulus and adjusted to match it. As long as there is a significantly large discrepancy between the internal representation and the external stimulus, the infant continues to look at the external stimulus. As this discrepancy falls, the infant becomes less interested in the external stimulus. In the autoencoder model, this is equivalent to the network's correctly generalizing on output to match the network input (i.e., if the error on each of the 26 outputs is less than 0.5). In particular, we will use this criterion of generalization to measure the network performance on the category-learning task in Simulation 2.

In the simulations reported here we hope to establish two claims – namely:

- i) Simulation 1: that the use of a vector of 26 weighted spatial-frequency values, as described above, does, indeed, produce autencoder network results that are similar to those produced by infants tested on the same images and
- ii) Simulation 2: that the reduced visual acuity produced by largely eliminating high-spatial frequency information from the input (i.e., "blurry" vision) actually significantly improves the network's ability to categorize the images presented to it.

Simulation 1: The adequacy of Gabor-filtered spatial-frequency input

In the first simulation we used the dog/cat stimulus set used in French et al. (2001). These authors used an encoding technique developed in Mareschal and French (1997) and Mareschal et al. (2000) in which 10 features of the animal images were measured and used as input to a 10-8-10 autoassociative network. Using feature-based input to this autencoder, we obtained categorization results that qualitatively matched experimental data with infants. In contrast, in the present simulation, we decomposed each image into a vector of values consisting of the energy values from each Gabor filter for a given orientation and spatial frequency. These values correspond, at least approximately, to what V1 neurons are known to "perceive."

Each value of the 26-element vector represents an "energy" level associated with that particular spatial frequency. For this simulation, frequencies above 3-4 cycles per degree of visual arc are given a very low

energy value (very high frequencies, i.e., those above 7.1 cycles/degree are simply removed), which means that they contribute very little to the overall input vector (i.e., they contribute very little to the overall characterization of the image). The removal of this high spatial-frequency information was done to simulate the reduced visual acuity of 3-4 month old infants (Courage & Adams, 1995).

The simulation reported here was done on a standard 26-16-26 feedforward backpropagation autoencoder network (learning rate: 0.1, momentum: 0.9, Fahlman offset: 0.1). The stimulus set and the training regime was identical to that used in French et al. (2001). (It is important to recall that in French et al., 2001, the Dog stimuli were selected to be the less varied category, while the exemplars making up the Cat category were chosen to be considerably more varied than the dogs.)

Networks were trained in batches of 2 patterns for a maximum of 250 epochs. This simulated familiarization with pairs of pictures for a fixed period before being presented with a new familiarization pair. All results were averaged over 100 runs.

Figure 3a: Network generalization errors on novel cats/dog exemplars as a function of familiarization category.

Figure 3b: Corresponding results for 34 month old infants

Figure 3a shows the model's generalization error to novel exemplars of cats and dogs as a function of whether they were trained on cats (the broad category) or on dogs (the narrow category). Networks trained (i.e., familiarized) with cats show very little difference in error (hence predict little difference in

infant looking times) when tested with a novel cat or a dog. In contrast, networks originally trained with dogs show significantly more error ($F(1, 198)=13.4$, $p<0.0005$) when tested with a novel cat than when tested with a novel dog (suggesting a preference for looking at a novel cat vs. a novel dog). Figure 3b shows the corresponding attentional asymmetry in 3-4 month old infants, as reported in French et al. (2001).

These simulation results using Gabor-filtered spatial frequency data allow us to conclude that the use of this type of spatial frequency data produces a reasonable fit to data. Most importantly, this result allows us to circumvent the thorny issue of using a particular set of "high-level" feature measurements (ear length, eye separation, etc.) to characterize the images used in the simulations.

Simulation 2. Improved categorization with reduced visual acuity

Does the autoencoder model of infant categorization (Mareschal & French, 1997; Mareschal et al., 2000) show improved categorization performance (at least on the dog/cat basic-level category images used in French et al., 2001) when "reduced acuity" input is used compared to "full acuity" input? The answer is that categorization performance is, indeed, enhanced, as we will show below.

To reiterate, the key idea of this simulation, which at first blush seems rather counter-intuitive: categorization performance for basic-level categories (Rosch et al., 1976) should be better *without* high spatial frequency information. This information is rather akin to noise in the input since, while it does indeed add information to the signal, it is not needed for accurate basic-level categorization. This extraneous information thus makes it more difficult (for the infant or for the network) to make use of the lower spatial frequency information that is, in fact, essential to basic-level categorization.

We used the same network as in Simulation 1, with an identical parameter set. We first ran the network (100 independent runs) with input data that contained all of the spatial-frequency information in the images. We then ran the network again (100 independent runs) with input data from which most of the high-spatial frequency information had been removed, as described above. The network was trained for 250 epochs on the training stimuli, as in Simulation 1.

As can be seen in Figure 4, whether the network was trained on Cats or Dogs, whether it was tested on novel dogs or novel cats, its categorization performance is significantly poorer when the input signal also contains high spatial frequency information compared to input with the high spatial frequencies removed.

It is also important to note that in the reduced visual acuity condition, we continue to see a significant difference in error (corresponding to

Figure 4. More information is not always better information, at least for basic-level categorization. The addition of high spatial frequency information makes correct basic-level categorization *more* difficult for the network.

attention in infants) when the network is trained first on dogs (in these experiments, the narrow category) and then sees a new cat, compared to when the network is first trained on cats (the broad category) and then sees a new dog.

Basic-level categories and incrementally increasing cognitive load

It is important to note that reduced acuity should improve categorization learning in the case of basic-level categories, but not subordinate-level categories. To see why this would be true we need to refer to Rosch et al.'s (1976) definition of "basic-level" categories. This level of categorization is the level for which the ratio of between-category variance to within-category variance is the highest. In other words, between-category variance is high with respect to within-category variance, which is generally relatively low. Within-category variance increases as fine-grained details of category exemplars increase. But these finer details are revealed only by the high spatial frequencies. For this reason, a decreased visual acuity that consists of partially or completely removing high-spatial frequency information, will decrease within-category variance and leave between-category variance largely unchanged. This would improve the learning of basic level categories, but would make it difficult, if not impossible, for 34 month old infants to learn categories that depend on high spatial frequency information. This applies, in particular, to subordinate-level categories.

Having *already learned* a certain number of basic-level categories under conditions of reduced visual acuity, when the high spatial frequency

apparatus does begin to come on-line at around 7 to 8 months of age (Kellman & Arterberry, 1998), the infants will be in a better position to then do more refined (i.e., subordinate-level) category learning. Thus, rather than having to confront all of the information associated with a particular category at once, the limitations of visual acuity of the infants' immature visual system first helps the infant to distinguish broader categories. Once these have been learned (or partially learned), then their visual/cognitive apparatus is then ready to build on this knowledge by incorporating the fine-grained details, perceived through high spatial frequency perception, that characterize subordinate expert-level categorization. The overall results of the simulations are thus consistent with a differentiation-driven view of early category development (Quinn & Johnson, 1997, 2000).

Furthermore, these results are entirely consistent with Archambault, Gosselin, & Schyns (2000), who showed that basic-level categorization seems to be more resistant to changes in viewing distances than that of subordinate-level categorization. This is because of the fact that as an object recedes from the viewer, information about details (i.e., high spatial frequency information) is lost, whereas low-spatial frequency information is not. Since basic-level categorization is largely based on the latter, we would expect more resistance to change of this type of categorization compared to subordinate-level categorization, where features are, indeed, essential.

A Prediction of the Model

A simple prediction emerges from these results. By manipulating the amount of high-frequency information in test images, it should be possible to vary infants' responses to these items after familiarization on a standard set of basic-level categories. So, for example, consider the Dog/Cat stimuli from the experiment by Quinn et al. (1993), in which the Dog category largely subsumes the Cat category. Under normal circumstances when infants are familiarized with cats, then shown a novel dog and a novel cat, they devote significantly more attention to the novel dog than to the cat. But were we to choose a novel dog and a novel cat whose differences were based largely on high spatial frequency information, we would expect the previously observed novelty preference to disappear, even if for us, adults, the two animals were quite different, one clearly being a dog, the other, clearly a cat.

Conclusion

In an extension of work done by Mareschal & French (1997), Mareschal et al. (2000) and French et al. (2001), we have been able to show that there is no need to use feature-based characterizations of the stimuli presented to the encoder network. Autoencoder results using Gabor-filtered input

corresponding approximately to the set of frequencies that the human visual system is known to use also produce a good approximation to categorization results in infants. We have also modeled a rather counter-intuitive learning advantage for basic-level categories that arises from reduced acuity input. Finally, based on the results of our autoencoder model of infant categorization and on the results we obtained using reduced acuity input, we have suggested experiments that might be performed on infants to further examine the validity of this model.

Abstract

This paper describes a computational model which simulates the change in the use of optional infinitives that is evident in children learning Dutch as their first language. The model, developed within the framework of MOSAIC, takes naturalistic, child directed speech as its input, and analyses the distributional regularities present in the input. It slowly learns to generate longer utterances as it sees more input. We show that the developmental characteristics of Dutch children's speech (with respect to optional infinitives) are a natural consequence of MOSAIC's learning mechanisms and the gradual increase in the length of the utterances it produces. In contrast with Nativist approaches to syntax acquisition, the present model does not assume large amounts of innate knowledge in the child, and provides a quantitative process account of the development of optional infinitives.

The Optional Infinitive Stage

One phenomenon which has received considerable attention in the area of syntax acquisition is the so-called *Optional Infinitive (OI) stage* (Wexler, 1994, 1998). Children in the OI stage of development use a high proportion of (root) infinitives, that is, verbs which are not marked for tense or agreement. In English, root forms such as *go*, or *eat* are infinitive forms, whereas *ate* or *goes* are marked for tense and agreement + tense respectively. Verbs which are marked for agreement or tense are known as *finite* verbs. (Technically, infinitives are a subclass of the class of *non-finite* verb forms, which also includes past participles and progressive particles).

Another feature of the OI stage is that children often omit subjects from their sentences. That is, children will produce utterances such as *throw ball* from which the subject (*I*) is absent. While the proportion of infinitives is (considerably) higher than for adult speech, children in the OI stage do show competence regarding other syntactic attributes of the language. Typically, children will not make errors in the basic verb-object order. English-speaking children, for instance, will say *throw ball*, but not *ball throw*. One puzzling feature of the OI stage is that children produce both inflected and uninflected forms in contexts requiring the inflected form, but do not produce finite forms in nonfinite

contexts. The fact that children use both inflected and uninflected forms shows that it is not the case that they simply don't know the inflected forms.

The optional infinitive stage has been shown to occur in many different languages, which can differ considerably in their underlying syntactic properties, and children do show competence regarding these syntactic properties. Different languages also differ with respect to how pronounced the OI stage is. Since most verb forms in English are not distinguishable from non-finite forms, it is relatively difficult to distinguish optional infinitives from grammatically correct utterances. In other languages (e.g. Dutch), the number of unambiguously finite forms is larger, and as a result the optional infinitive stage is more pronounced.

Wexler (1998) has proposed a Nativist account of why children in the optional infinitive stage produce a large number of non-finite forms. In accordance with Chomsky's theory of Universal Grammar (Chomsky 1981), he theorizes that children in the optional infinitive stage actually know the full grammar of the language. The only thing they do not know is that Agreement and Tense are obligatory. This approach accounts for the fact that children produce both correct finite forms and incorrect (optional) infinitives. It also explains why children rarely produce other types of errors. Finally, its great strength is that it unifies across languages where children clearly use optional infinitives despite differences in their underlying grammar. However, there are also a number of problems with Wexler's account.

Firstly, Wexler's theory does not give a process account of developmental change in the use of optional infinitives. He assumes this to be due to *maturation*.

Secondly, the theory makes very limited quantitative predictions. It only predicts that the optional infinitive stage occurs, and that children will stop making optional infinitive errors at some point. It makes no specific predictions regarding the time course of this development, or related changes in other attributes.

Thirdly, the theory assumes a large amount of innate knowledge in the child (the theory assumes that the child does not know that inflection is obligatory, but otherwise knows the full grammar of the language).

An obvious alternative to Wexler's theory is that children learn the grammar of a language through exposure to that language. Wexler discounts this kind of learning-based approach on the grounds that the grammar is too difficult to learn, that the optional infinitive stage lasts too long (years), and that, although children produce both correct and incorrect forms, when they use finite forms, they use them correctly (Wexler, 1994).

In this paper, we aim to show that the dynamics of the optional infinitive phenomenon can be simulated using a simple learning mechanism which performs a distributional analysis of naturalistic input. Earlier versions of the model have already been shown to simulate the basic optional infinitive phenomenon in both English (Crocker, Pine & Gobet, 2001) and Dutch (Freudenthal, Pine & Gobet, 2001). Whereas the earlier versions modelled one specific stage in development, the present model aims to simulate the *developmental change* that is apparent in the use of optional infinitives.

There are a number of reasons for choosing Dutch as the target language. Firstly, as was mentioned, in adult speakers' Dutch, unambiguous finite forms are far more frequent than they are in English. In English, in the present tense, only the third person singular can be distinguished from the infinitive form. In Dutch, the first, second and third person singular are unambiguously finite. If, for instance, an English speaking child produced *I throw ball*, it would be unclear whether the verb *throw* was an infinitive form. The Dutch equivalent *ik gooi bal* would be classified as a finite form, because *gooi* is different from the infinitive *gooien*. Thus, the number of unambiguously finite forms is larger in Dutch than in English. (This suggests that developmental change in the use of optional infinitives is likely to be more pronounced in Dutch than it is in English, which makes the simulation of Dutch child language more informative as a modelling exercise.) A second reason for using Dutch is that detailed data regarding this development are available. Wijnen, Kempen & Gillis (2001) have analysed the corpora of two Dutch speaking children and have shown that the proportion of root infinitives decreases from around 90% to roughly 10% between the ages 1;6 and 3;0. By comparison, root infinitives are used in less than 10% of adults' utterances. Wijnen et al. concluded that the frequency of occurrence of optional infinitives in the child's speech was related to frequency, and utterance position, as well as lexical transparency.

A third reason for choosing Dutch as the target language is that Dutch grammar is relatively complex when considering finiteness of verb forms. Dutch is what is known as an SOV/V2 language. This means that the verb in Dutch can take one of two positions, depending on its finiteness. A non-finite verb takes the

sentence final position, whereas finite verbs take the second position. Therefore, in the sentence

Ik gooi een bal (1)
(I throw a ball)

the verb *gooi* (*throw*) is finite and takes second position. In the construction

Ik wil een bal gooien (2)
(I want a ball throw/ I want to throw a ball)

the verb *gooien* is a non-finite form, and takes sentence final position. (The auxiliary *wil* is finite and takes second position.) In English, which is an SVO language, verb position is not dependent on the finiteness of the verb. If a model is to learn from the distribution of naturalistic speech input, then the production of a large number of infinitives while respecting the overall grammar would appear to represent a greater challenge in Dutch than in English.

MOSAIC

MOSAIC (Model of Syntax Acquisition In Children) is an instance of the CHREST architecture, which in turn is a member of the EPAM (Feigenbaum & Simon, 1984) family of models. CHREST models have successfully been used to simulate novice-expert differences in chess (Gobet & Simon, 2000), as well as several phenomena in language acquisition (Jones, Gobet & Pine, 2000a, 2000b; Crocker, Pine & Gobet, 2001, 2002; Freudenthal, Pine & Gobet, 2001, 2002). We will now give a brief description of MOSAIC. A more detailed description of the model can be found elsewhere in this volume (Freudenthal, Pine & Gobet 2002). The model we have used in these simulations is identical to the one that Freudenthal et al. (2002) used for the simulation of a different phenomenon (Subject Omission) in another language (English).

The basis of the model is a discrimination net, which is used to store the input that is fed to the model. The network is an n-ary tree which is headed by a root node. Utterances that the model sees are encoded by sequences of nodes in the network.

The model encodes the fact that word *a* has been followed by word *b* in the input by creating a node for word *b* under the node for word *a*. The fact that word *a* has preceded word *b* is similarly encoded. Fig. 1 may illustrate the basic MOSAIC network. Apart from the standard links between words that have followed each other in utterances previously encountered, MOSAIC also employs *generative links*. Generative links connect nodes that are distributionally similar. When two nodes (phrases) have a high likelihood of being preceded and followed by the same words in the input, a generative

link is created between them. Since distributionally similar phrases are likely to belong to the same word class, generative links that develop end up linking clusters of nodes that represent different word classes. The induction of word classes on the basis of co-occurrence statistics is the only mechanism that MOSAIC employs for representing syntactic rules. The main importance of generative links lies in the generation of utterances from the model. In generation, words that share a generative link can be substituted, thus allowing the model to generate novel utterances. Again, the reader is referred to Freudenthal, Pine & Gobet (2002) for details regarding generation. One point worth mentioning here is that the model will only output utterances that contain an end marker (i.e. where the utterance final phrase has occurred in a sentence final position in the input). Several authors have suggested that sentence final position is particularly salient, and that children are more likely to produce utterances that have occurred in sentence final position (Shady & Gerken, 1999; Naigles & Hoff-Ginsberg, 1998).

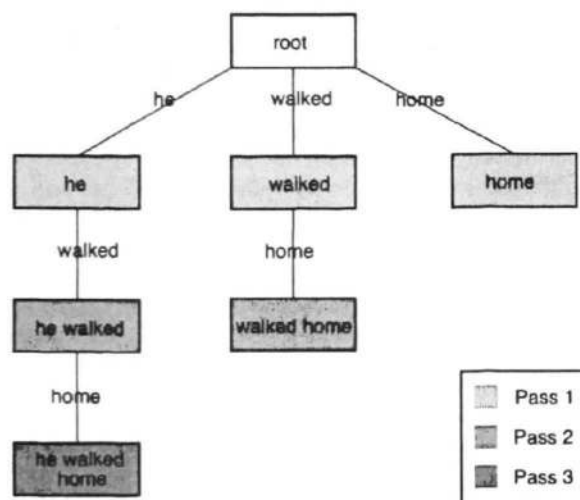

Fig. 1: MOSAIC learning an input

The model we used for these simulations is an extension of that used in Freudenthal, Pine & Gobet, (2001), which simulates the children's performance in Dutch at one specific point in time. This version of the model has also been shown to produce both root infinitives and correct inflected forms in English (Crocker, Pine & Gobet, 2001). The main difference between this and the previous version of the model is that the present model learns much more slowly. By using a slow learning rate, and iteratively feeding input to the model and analysing its resulting output, we were able to model consecutive stages of development. In the previous version, a word was encoded on the first

occasion it was seen, which resulted in a model with an MLU (Mean Length of (output) Utterance), that was comparable to that of a child that has passed the OI stage. In the present version, the probability of creating a node is dependent on the size of the network (a measure of the linguistic knowledge or vocabulary size of the child), and the length of the phrase that is being encoded. More specifically, the probability of creating a node is given by the following formula:

$$NCP = \left(\frac{*nodes_in_net*}{50,000} \right)^{length_phrase}$$

It will be apparent from the formula above that the probability of creating a node is very low if the network is small (i.e., the number of nodes in the net is low). As the number of nodes in the net grows, this probability will increase. A second point to note is the occurrence of the length of the phrase (number of words) in the exponent. This has the effect of lowering the probability of creating nodes that encode longer phrases. The value 50,000 has been chosen somewhat arbitrarily. Its main role is to ensure that the difference in node creation probability for short and long utterances decreases as a function of the size of the net. As the number of nodes in the net approaches 50,000 (a typical number for a saturated model given the Dutch input used here), the base number in the formula approaches one, and thus the weight of the exponent diminishes. One additional remark must be made about this formula: phrases that occurred in utterance final position (i.e., contained an *end marker*), were treated differently from other utterances in that their length (for calculation of the NCP) was decreased by 0.5. This constitutes an *end marker bias* in learning, rather than at production. It has been argued that utterance final phrases are learned more easily than non-utterance final phrases (Wijnen, Kempen & Gillis, 2001).

The Simulations

The data that were simulated were taken from Wijnen, Kempen & Gillis (2001). Wijnen et al. analysed two Dutch corpora of child and adult speech (the corpora of Matthijs and Peter and their mothers). The corpora consisted of transcribed tape recordings of speech between mother and child. For Matthijs, the recordings were made between the ages 1;9 and 2;11. For Peter they were made between 1;7 and 2;3. The children's MLU (Mean Length of Utterance) ranged from 1 to roughly 3. Wijnen et al. analysed the corpora with respect to the presence of the optional infinitive phenomena in both the mother's and the children's speech. On the basis of the children's data, four developmental stages were identified, and the proportion of finite, non-finite and discontinuous finites

(see below) was assessed. Since the corpora that Wijnen et al. analysed are available in the CHILDES data base (MacWhinney & Snow, 1990), we had access to the same corpora, and used these (maternal corpora) as input for the model.

In order to compare the output of the model to the children's speech, we ran the input through the model several times. After each run of the model, we generated output, and compared the MLU of the model with the child's MLU in the developmental stages that Wijnen et al. identified. We then selected for further analysis those output files that most closely matched the children's MLU for the four developmental stages. The actual analysis performed was similar to that of Wijnen et al. Firstly, we selected those utterances that contained one or more verb forms. We then classified these utterances as finite, non-finite or discontinuous finite. In doing so, we used the following criteria:

- An utterance is considered *non-finite* if it contains only non-finite verb forms.
- An utterance is considered *finite* if it contains only finite verb forms.

- An utterance is considered a *discontinuous finite* if it contains both a non-finite, and a finite form (e.g. a finite auxiliary).

There were some small differences from Wijnen et al.'s analysis. The most notable difference is that Wijnen et al. removed all forms resembling imperatives, starting with the early two word stage. When coding actual speech, this is relatively easy to do, since context allows one to disambiguate. Since the model's output does not provide this context, the classification remains somewhat ambiguous. We therefore decided not to remove forms resembling imperatives.

Results

Figure 1 shows the data and the simulations for Matthijs and Peter. The model shows a considerable drop (around 50%) in the proportion of non-finites for both input sets. For the children, the corresponding drop is 80-85%. Given the fact that we are using naturalistic input to model the development of children's speech, and the fact that we used an identical model for both children (i.e. no parameters were adjusted) we consider

Fig. 2a: Data for Matthijs

Fig. 2b: Model for Matthijs

Fig. 2c: Data for Peter

Fig. 2d: Model for Peter

Figure 2: Distribution of root infinitives and (discontinuous) finites as a function of MLU for Matthijs, Peter, and their respective model.

this figure promising. (Note however, that we report five rather than four data points for the models. The last data point reflects an MLU larger than that for the children in the final stage, and is included to show that the proportion of non-finites continues to decrease.)

What mechanism is responsible for this drop in the model's output? The thing to note is that non-finite forms take sentence-final position in Dutch, and that the model is biased towards generating (and encoding) phrases that occurred in sentence-final position. The formula for calculating the node creation probability ensures that early on, the model will encode relatively short utterances that occurred in sentence-final position. If these utterances contain a verb, it will (in Dutch) most likely be a non-finite form. These non-finite forms may have been part of an auxiliary + verb construction (e.g. *He wants to build a house*). Since the model can generate partial utterances, it can learn the root infinitive *build a house* from this (discontinuous) finite form. Therefore, a high proportion of non-finite forms is expected in the early stages of the model's development. As the model sees more and more utterances, the number of nodes in the net will increase, and the probability of creating a node will also increase. As a result, longer and longer utterances will be encoded in the network. As the encoded utterances increase in length, they will be more likely to include words that occur early in the utterance. Since finite forms take second position in Dutch, the number of finite forms will increase as the model starts generating longer utterances. Note that this also means that root infinitives will slowly be replaced by discontinuous finites. Where the model may have output the root infinitive *build a house* early on, it will be able to output the discontinuous finite *he wants to build a house* as the size of the net increases.

Table 1: Proportion of correct Object-Verb orderings for the model as a function of finiteness (averaged over developmental phase).

	Finites	Non-Finites
Matthijs	.94	.91
Peter	.96	.93

Given that the model simulates the basic optional infinitive phenomenon, we now need to assess whether it conforms to the other criteria of the optional infinitive stage. Tables 1 and 2 show the proportion of correct verb placement and the position of the object relative to the verb. It is evident, that, in the majority of cases, the model uses the correct placement, indicating that it is sensitive to basic Dutch grammar.

The fact that the model gets the basic word order right in the majority of the cases is perhaps not very surprising. After all, the input that the model learns

from has the correct word order. This is not a trivial result however, as the fact the children correctly produce the correct word order has been taken as evidence by Wexler (1994, 1998) that the child knows the actual grammar.

Table 2: Proportion of correct verb placement for the model as a function of finiteness (averaged over developmental phase).

	Finites	Non-Finites
Matthijs	.85	.95
Peter	.88	.97

Though these results are very promising, especially considering the fact that we are using naturalistic input to simulate actual children's speech, some issues require attention. For both children, the proportion of non-finites is underestimated for stage 2, and overestimated for the later stages. Possible causes for the underestimation in the early stages may lie in the fact that Wijnen et al. removed forms resembling imperatives as of stage two (which may also explain the relatively low proportion of non-finites in stage one in the data). We did not do this. This underestimation may be exacerbated by the fact that the model produces relatively few utterances early on, thus making it relatively sensitive to small changes. A second, possibly more likely cause may be that there are additional factors that cause the high proportion of non-finites in the children. Wijnen et al. claim, on the basis of a regression analysis, that frequency of occurrence alone is not enough to explain the high incidence of non-finite forms. They suggest that non-finite forms are learned more easily and attribute this to lexical transparency. Since MOSAIC does not employ any semantics, we cannot model this effect. Regarding the later stages, one possible cause for the overestimation is the fact that MOSAIC has a limited ability to unlearn. That is, at any stage, when the model generates output, it will generate all the utterances it can. Thus, once the model has learnt to generate *he wants to build a house*, it will also (still) generate *build a house*.

Mechanism for change

The model shows a drop in the proportion of non-finites of roughly 50%. We can now ask ourselves what has caused this change. Two possible explanations come to mind. Firstly, as the model learns, the MLU of the generated utterances increases. As explained earlier, if the generated utterances adhere to Dutch grammar, an increase in the proportion of finites is expected. A second possible cause lies in the proportion of generated (rather than rote learned) utterances. As the model's MLU increases, so does the proportion of generated utterances. This may result in a

disproportionate growth in the number of finite utterances. (Since finite forms are more frequent, a relatively large proportion of the generated utterances contain finite verbs.) While a regression analysis showed that the increase in MLU alone explained 90% of the variance in the proportion of finite utterances, and the proportion of generated utterances explained an additional 6%, the correlation between generativity and MLU was relatively large, which might decrease the sensitivity of this analysis. We therefore assessed the proportion of non-finites in rote utterances only. This increased the proportion of non-finites in the last stage by 10% for Peter's model, and by 20% for Matthijs' model. Apparently, the role of generativity is greater than the regression analysis suggests.

Conclusions

The model described in this paper clearly captures the development that is evident in Dutch children's use of infinitive verb forms. In doing so, the model provides both a process model, and a quantitative account of this transition. Furthermore, it shows that a considerable portion of the drop in non-finite forms can be explained by a learning mechanism that emphasizes utterance final phrases, and an increase in MLU, although the process is likely to be augmented by other considerations (as witnessed by the relatively poor fit for the very early and late stages). While it does not solve the learnability problem, and as such is probably too simplistic a model of syntax acquisition, the present simulations clearly show that the Optional Infinitive phenomenon does not, in itself constitute evidence for the innateness of syntactic knowledge. As such, it supports the suggestion that children's sensitivity to the distributional characteristics of their linguistic environment may aid them in learning their native language. In order to further test this suggestion, it will be necessary to assess to what extent the present findings generalise to other languages. This may also suggest possible extensions to the model.

Subject Omission in Children's Language: The Case for Performance Limitations in Learning

Daniel Freudenthal (DF@Psychology.Nottingham.Ac.Uk)

Julian Pine (JP@Psychology.Nottingham.Ac.Uk)

Fernand Gobet (FRG@Psychology.Nottingham.Ac.Uk)

University Park, Nottingham, NG7 2RD UK

Abstract

Several theories have been put forward to explain the phenomenon that children who are learning to speak their native language tend to omit the subject of the sentence. According to the pro-drop hypothesis, children represent the wrong grammar. According to the performance limitations view, children represent the full grammar, but omit subjects due to performance limitations in production. This paper proposes a third explanation and presents a model which simulates the data relevant to subject omission. The model consists of a simple learning mechanism that carries out a distributional analysis of naturalistic input. It does not have any overt representation of grammatical categories, and its performance limitations reside mainly in its learning mechanism. The model clearly simulates the data at hand, without the need to assume large amounts of innate knowledge in the child, and can be considered more parsimonious on these grounds alone. Importantly, it employs a unified and objective measure of processing load, namely the length of the utterance, which interacts with frequency in the input. The standard performance limitations view assumes that processing load is dependent on a phrase's syntactic role, but does not specify a unifying underlying principle.

Subject Omission

Children who are acquiring English often produce sentences with missing subjects, like those shown below.

Hug Mummy
Play Bed
Writing Book
See Running

While these examples clearly do not adhere to adult English grammar, many contemporary theories of child language assume that children produce their sentences on the basis of an abstract grammar. Theories differ with respect to how much the hypothesized grammar differs from the adult grammar. According to the *pro-drop hypothesis* (Hyams, 1986; Hyams & Wexler, 1993), children represent a grammar that is different from the adult grammar in that it allows *null subjects*. In this respect, children's grammar resembles that of

adult Italian and Spanish speakers. Other authors have argued that children actually possess the correct adult grammar, but drop subjects because they have difficulty expressing the (correct) underlying form due to some kind of processing bottleneck (L. Bloom, 1970; L. Bloom, Miller & Hood, 1975; Pinker, 1984; P. Bloom 1990; Valian, 1991). Thus, a child producing an utterance is thought to represent a grammatically correct underlying structure, but, due to performance limitations, some elements have a lower probability of being expressed than others.

A number of phenomena have been cited as evidence for the performance limitations view. P. Bloom (1990) showed that, in utterances with a subject, the length of the Verb Phrase (VP) is shorter than it is in utterances without a subject. The load associated with the provision of a subject is thought to decrease the likelihood of expressing a longer verb phrase. Along similar lines, the length of the VP is greater when the subject is a pronoun, than when it is a noun. This is thought to result from the fact that pronouns are phonetically shorter, and the fact that non-pronominal subjects may be longer than pronominal ones. L. Bloom (1970) has also found that subject omission is more likely in negated sentences or in sentences with relatively new (unfamiliar) verbs. Presumably, the load associated with negation and novel verbs is such that it induces subject omission.

While the performance limitations view makes sense from an information-processing point of view, it is not very precise in its predictions (Theakston, Lieven, Pine & Rowland, 2001). Performance limitations accounts also tend to be rather ad hoc in nature. Given the imprecise nature of performance limitations, it becomes all too easy to posit a greater processing load whenever the provision of a certain element leads to a greater likelihood of the omission of another, especially when there is an interaction with frequency. Furthermore, it is not clear whether an explanation of the patterns in the data requires a limitation in production coupled with full knowledge of a language's grammar (as the performance limitations view typically has it). In fact, as Theakston et al. point out, performance limited *learning of lexical items* (independent of syntactic complexity) may well give rise to the same pattern of

results without the need to assume a full representation of the grammar, and a different processing load for various types of grammatical roles. The present paper aims to test these claims by seeing to what extent a performance limited distributional analysis of naturalistic input can account for the pattern of omission and provision of grammatical categories that is found in children's speech. To this end, we aim to simulate the effects that P. Bloom (1990) attributes to performance limited production. We will now introduce the model we have used for these simulations.

MOSAIC

MOSAIC (Model of Syntax Acquisition In Children) is an instance of the CHREST architecture, which in turn is a member of the EPAM family of models. CHREST models have successfully been used to model phenomena such as novice-expert differences in chess and computer programming. In language acquisition, MOSAIC has been applied to the modelling of the use of optional infinitives in English and Dutch, the learning of sound patterns and the Verb Island phenomenon. Due to space limitations, we refer the reader to another paper in this volume for the relevant references (Freudenthal, Pine & Gobet, 2002).

The basis of the model is a discrimination net, which can be seen as an index to Long-Term Memory. The network is an n-ary tree, headed by a root node. Training of the model takes place by feeding utterances to the network, and sorting them (see Figure 1). Utterances are processed word by word. When the network is empty, and the first utterance is fed to it, the root node contains no test links. When the model is presented with the utterance *He walked home*, it will create on its first pass three test links from the root. The test links hold a key (the test) and a node. The key holds the actual feature (word or phrase) being processed, while the node contains the sequence of all the keys from the root to the present node. Thus, on its first pass, the model just learns the words in the utterance. When the model is presented with the same sentence a second time, it will traverse the net, and find it has already seen the word *he*. When it encounters the word *walked* it will also recognize it has seen this word before, and will then create a new link under the *he* node. This link will have *walked* as its key, and *he walked* in the node. In a similar way, it will create a *walked home* node under the primitive *walked* node. On a third pass, the model will add a *he walked home* node under the *he walked* chain of nodes. The model thus needs three passes to encode a three-word phrase with all new words. (For expository purposes, here we assume that a node is created with a probability of 1. As is explained under *learning rate*, this probability is actually lower and dependent on a number of factors). Figure 1 shows the

development of the net through the three presentations of the sentence.

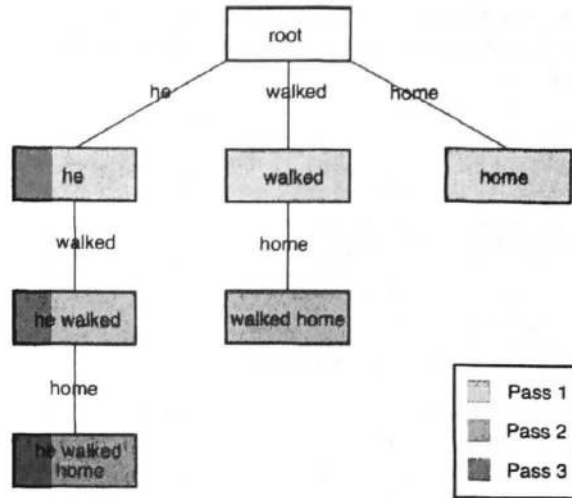

Figure 1: MOSAIC learning an input.

As the model sees more input, it will thus encode longer and longer phrases. Apart from the standard test links between words that have followed each other in utterances previously encountered, MOSAIC employs *generative* links that connect nodes that have a similar context. Generative links can be created on every cycle. Whether a generative link is created depends on the amount of overlap that exists between nodes. The overlap is calculated by assessing to what extent two nodes have the same nodes directly above and below them (two nodes need to share 10% of both the nodes below and above them in order to be linked). This is equivalent to assessing how likely it is that the two words are preceded and followed by the same words in an utterance. Since words that are followed and preceded by the same words are likely to be of the same word class (for instance Nouns or Verbs), the generative links that develop end up linking clusters of nodes that represent different word classes. The induction of word classes on the basis of their position in the sentence relative to other words is the only mechanism that MOSAIC uses for representing syntactic classes.

The main importance of generative links lies in the role they play when utterances are generated from the network. When the model generates utterances, it will output all the utterances it can by traversing the network until it encounters a terminal node. When the model traverses standard links only, it produces utterances or parts of utterances that were present in the input. In other words, it does *rote* generation. During generation, however, the model can also traverse generative links. When the model traverses a generative link, it can

supplement the utterance up to that point with a phrase that follows the node that the current node is linked to. As a result, the model is able to generate utterances that were not present in the input. Figure 2 gives an example of the generation of an utterance using a generative link.

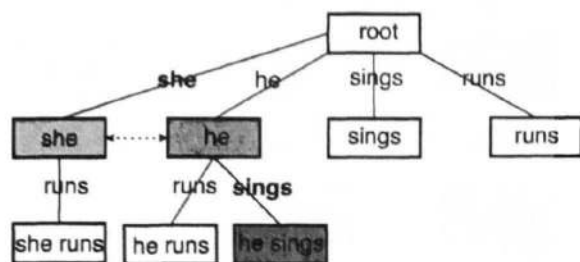

Figure 2: Generating an utterance. Because *she* and *he* have a generative link, the model can output the novel utterance *she sings*. (For simplicity, preceding nodes are ignored in this figure.)

Learning Rate

MOSAIC does not simply learn all the utterances it encounters. The probability of the creation of a node is dependent on the size of the net and the length of the utterance it encodes. This has the effect of making the learning process frequency sensitive. If an utterance is seen more often, it has a higher probability of being created. Finally, phrases that occur in an utterance final position in the input (have an *end marker*) have a higher probability of being encoded. The precise formula governing learning rate is given elsewhere in this volume (Freudenthal, Pine & Gobet, 2002).

Performance Limitations in MOSAIC

The only performance limitations in MOSAIC are the following:

- Frequency: high frequency items have a higher likelihood of being encoded, and thus feature in longer utterances
- Short phrases have a higher likelihood of being encoded than long phrases
- Utterance final phrases have a higher likelihood of being encoded.
- An utterance will only be produced (generated) if its final phrase has occurred in sentence final position in the input.

It may be appropriate to point out that these performance limitations are plausible from general theorizing in the cognitive psychology and learning literature. Huttenlocher et al. (1991) provide evidence for the effect of frequency on vocabulary learning. Evidence for the importance of sentence final position

has been provided by Naigles & Hoff-Ginsberg (1998) and has been attributed to prosodic highlighting of the sentence final position (Shady & Gerken, 1999). In contrast to the standard performance limitations view, processing load in MOSAIC does not vary as a function of grammatical role. Also note that the version of MOSAIC used for these simulations is identical to that which Freudenthal, Pine & Gobet (2002) used for the simulation of the optional infinitive phenomenon in Dutch. No free parameters were fitted to obtain these results.

Subject Omission in MOSAIC

MOSAIC creates utterances without subjects because the model can output partial utterances, provided that the utterance final element has occurred in a sentence final position in the input. As a consequence, constituents that take a position early in the sentence, have a higher probability of being omitted than those that take a position further *downstream*. Since the subject takes first position in English, it has the highest likelihood of being omitted. However, this prediction is not tied to the English language. MOSAIC would generate utterances with omitted subjects in all languages that have the subject as the first element in their underlying word order.

Method

In order to simulate the data presented by P. Bloom (1990), two MOSAIC models were trained using corpora of maternal speech available in the CHILDES database (MacWhinney & Snow, 1990). We used the files of Anne and Becky. The mean length of utterance (MLU) in the output generated from the models was 2.87 for Anne's model, and 3.41 for Becky's model. In line with Bloom's analysis, we limited our analysis to utterances which could not be interpreted as imperatives. This is necessary as subjectless sentences in English are grammatical as imperatives (e.g. *Put it down*). Bloom selected a list of *nonimperative verbs* and *past tense verbs* for his analysis. Since these verbs cannot be used in an imperative form, sentences which contain a verb from these lists, and do not contain a subject, are true examples of subject omission. Tables 1 and 2 give the lists of verbs that were used for these analyses.

Table 1: Nonimperative verbs used for analysis

Care	Laugh	Miss
Cary	Laughs	Need
Fall	Like	See
Falls	Live	Sneeze
Forget	Lives	Want
Grow	Love	Wants
Know	Loves	

In line with Bloom's analysis, we removed from our samples all questions, all utterances that contained the words *not* or *don't*, all utterances where the verb was not used in a productive way, and all utterances where the target verb was part of an embedded clause.

Table 2: Past tense verbs used for analysis

Ate	Fixed	Saved
Bit	Folded	Saw
Bought	Forgot	Sent
Broke	Found	Sharpened
Brought	Gave	Spilled
Came	Goed	Stepped
Caught	Ironed	Stopped
Closed	Left	Thought
Cooled	Lost	Threwed
Covered	Made	Took
Cried	Melted	Tored
Drinked	Pee-peed	Tripped
Dropped	Pulled	Turned
Dropt	Rode	Washed
Falled	Said	Went
Fell	Sat	Wrote

Table 3 gives the data for three children that Bloom reports and the two simulations (Anne's and Becky's model). It can be seen that for the children, the Verb Phrase length in utterances with a subject is shorter than in utterances without a subject. It can also be seen that MOSAIC readily simulates this result, and the size of the effect is quite comparable to that in the children. The difference in verb phrase length is statistically significant for both Anne's model ($t(330) = 4.82, p < .001$), and Becky's model ($t(314) = 4.64, p < .001$).

Table 3: Mean length of Verb Phrases in sentences with and without subjects

Child	With Subject	Without Subject
Adam	2.33	2.60
Eve	2.02	2.72
Sarah	1.80	2.46
Anne's Model	2.14	2.76
Becky's Model	2.58	3.31

MOSAIC obtains this result because the probability of learning an item in MOSAIC is dependent only on its frequency and length, and not on its grammatical role. There is thus no reason (apart from differences in frequency), why sentences with subjects should, on average, be longer (or shorter) than those without. The fact that verb phrases in utterances with subjects should be longer than verb phrases in utterances without a subject is a straightforward consequence of this fact.

A second analysis performed by Bloom was to look at the length of the verb phrase as a function of the type of subject (no subject, pronoun or non-pronoun). The reasoning was that, since the processing load of a subject is higher than that of a missing subject, and the processing load of a non-pronoun subject is higher than that of a pronoun (since the pronoun is both phonetically shorter as well as shorter in word length), this should again result in length effects on the Verb Phrase. The results of this analysis are shown in table 4.

Table 4: Mean length of Verb Phrase as a function of subject size

	No Subject	Pronoun	Non-Pronoun
Adam	2.60	2.55	2.25
Eve	2.75	2.30	2.00
Sarah	2.45	1.90	1.50
Anne's Model	2.76	2.45	1.60
Becky's Model	3.31	2.93	1.67

Again, it is clear that MOSAIC has no difficulty in simulating these results (though the size of the effect in MOSAIC appears to be slightly larger than in the children that Bloom analysed). The difference in verb phrase length between utterances with a pronoun subject and those with a non-pronominal subject is statistically significant for both Anne's model ($t(64) = 3.45, p < .001$) and Becky's model ($t(104) = 4.40, p < .001$). There are two possible reasons why MOSAIC might simulate this result. Firstly, non-pronoun subjects are on average slightly longer than pronoun subjects. Pronouns are by definition one word long, while non-pronoun NP's can contain determiners and adjectives. In fact, Bloom indicates that the average non-pronoun subject for the children he analysed was 1.16 words long. Secondly, pronouns have a higher frequency of occurrence than non-pronominal subjects. In MOSAIC, this increases the likelihood that they will be learnt, and the likelihood that they will feature in longer utterances. We decided to test these two explanations in MOSAIC by performing the analysis on non-pronominal subjects of length one and greater separately. As it turned out, only a small proportion of the non-pronominal subjects had a length greater than one. For non-pronominal subjects of length one, the size of the VP was 1.58 for Anne's model, and 1.88 for Becky's model¹. Both values are smaller than the VP length for pronoun

¹ One would expect the length of the verb phrase to increase when limiting this analysis to subjects of length 1. This is the case for Becky's model, but not for Anne's model. This is due to the fact that, for Anne's model, there were relatively few long non-pronominal subjects, but one of those that did occur had a particularly long verb phrase.

subjects. Given the low incidence of long non-pronominal subject in both these and Bloom's data, this clearly indicates that the lower complexity effect that Bloom attributes to the fact that pronouns are phonetically shorter, can be explained by frequency in the input. Note that MOSAIC does not employ a phonetic component. Phonetic differences can therefore not have contributed to MOSAIC's simulation of the effect.

The importance of frequency in the input as an explanation for the difference between pronouns and non-pronouns is also highlighted by a point made by Hyams & Wexler (1993). Though pronouns may be phonetically shorter, the process of assigning the referent to a (potentially ambiguous) pronoun may actually result in its processing load being higher, rather than lower. This would predict a shorter Verb Phrase length for pronominal than for non-pronominal subjects.

Subject versus Object Omission

It has often been shown that subjects are omitted more often than objects. In order to test how often objects are omitted, Bloom selected utterances which contain verbs that require an object, and calculated the proportion of object omission from these obligatory contexts. Table 5 shows this list of verbs.

Table 5: Verbs that take obligatory objects.

Bought	Ironed	Saved
Broke	Like	Saw
Brought	Love	See
Caught	Loves	Sharpened
Covered	Made	Thought
Drinked	Miss	Threwed
Fix	Need	Took
Folded	Pulled	Want
Found	Rode	Wants
Gave	Said	Washed

Table 6 compares the proportion of omitted subjects and objects from obligatory contexts (verbs from tables 1 and 2 for subjects, verbs from table 5 for objects). It can be seen that the proportion of subject omission is considerably higher than the proportion of object omission. The subject-object asymmetry was significant for both Anne's model ($\chi^2(1, N = 560) = 98.83, p < .001$), and Becky's model ($\chi^2(1, N = 548) = 125.97, p < .001$). Bloom suggests several possible causes for this asymmetry. Firstly, it may be due to pragmatic factors. Since subjects typically convey given information, while objects convey new information, it may be more pragmatically appropriate to omit subjects when processing capacity is limited. A second possible cause might be that there is a 'save the heaviest for last' bias.

This would result in subjects having a higher processing load than objects, and as a result, in them being omitted more often.

Table 6: Omission from obligatory contexts

	Subjects	Objects
Adam	57%	8%
Eve	61%	7%
Sarah	43%	15%
Anne's Model	64%	21%
Becky's Model	60%	14%

The explanation for the effect in MOSAIC is simple.

As a result of MOSAIC's performance limitations, a constituent is less likely to be omitted when it occurs further toward the end of the sentence. Since subjects take first position, and objects usually come after the verb, the probability of omitting an object is smaller than the probability of omitting a subject. Bloom goes on to suggest that the hypothesized processing asymmetry should cause other differences between subjects and objects. For example, since pronouns exert less of a processing load, more pronouns will occur in subject position than in object position. Table 7 shows the relevant data, both for Bloom's analysis, and MOSAIC's simulations. Again, the asymmetry is significant for Anne's model ($\chi^2(1, N = 243) = 8.08, p < .01$), and Becky's model ($\chi^2(1, N = 292) = 27.53, p < .001$).

Table 7: Proportion of overt pronominal Noun Phrases

	Subjects	Objects
Adam	41%	25%
Eve	36%	14%
Sarah	91%	33%
Anne's Model	47%	27%
Becky's Model	72%	40%

There is no specific reason why MOSAIC would predict this effect, but the pragmatic factors that Bloom mentions may well explain this result. Subjects tend to convey given information, and objects tend to convey new information. It certainly makes sense to introduce new information using a non-pronoun NP. The use of a pronoun requires the listener to resolve the referent of the pronoun. The use of a non-pronoun NP is usually less ambiguous, which aids the resolution process. In fact, several authors have argued that this is the preferred argument structure for English (Clancy, 2001). As such, it is not just a feature of child language, but is actually the preferred structure in adult language. The fact that MOSAIC simulates this result is simply a

reflection of the fact that it mimics the distribution of the input.

Conclusions

MOSAIC clearly simulates all the results that Bloom reports. MOSAIC is not an ad hoc model of subject omission, as it has already been shown to account for several phenomena in children's speech, and is firmly grounded in the CHREST/EPAM framework. Though MOSAIC has performance limitations, these reside mainly in the learning mechanism. Unlike the standard performance limitations view, MOSAIC does not assume full competence. In fact, MOSAIC has no built in knowledge regarding grammatical categories or roles. The effects arise in MOSAIC through a combination of performance limited distributional learning, and frequency sensitivity. Effects that are present in the input (such as a higher proportion of pronominal subjects than objects), are mimicked in MOSAIC's output because of the fact that it is a distributional analyser.

On a theoretical level, MOSAIC has two main strengths over the standard view of performance limitations. Firstly the definition of processing load in the standard view is somewhat ad hoc. If the provision of certain elements leads to a higher rate of subject omission, this is seen as evidence for a relatively high processing load of these elements. The actual reason for this high processing load then varies from effect to effect. Within MOSAIC, processing load is a function of the interaction of two objectively measurable variables: frequency in the input, and length of the phrase being encoded. When an item is more frequent in the input, it has a higher likelihood of being encoded, and therefore features in longer utterances that have a higher likelihood of being grammatical (i.e. including the subject). If two utterances have equal overall frequency, and one of the two includes a longer element (verb phrase), then some other element will necessarily be omitted. Since the subject is the first element in the sentence, this has a higher likelihood of being omitted.

Secondly, the standard performance limitations view assumes a large amount of innate knowledge in the child. For the simulation of these results, MOSAIC assumes no innate syntactic knowledge.

Does Positivity Bias Explain Patterns of Performance on Wason's 2-4-6 Task?

Abstract

In the standard form of Wason's (1960) 2-4-6 task, participants must discover a rule that governs the production of sequences of three numbers. Studies typically show success rates of approximately 20%, which Wason attributed to a cognitive deficit that he labeled 'confirmation bias'. In Tweney et al.'s (1980) formally equivalent Dual Goal (DG) form of the task, however, success rates are at least double to those seen on the standard task. If this facilitated performance could be accounted for, then this would go some way toward explaining the normally low performance on the standard problem. The present experiment examined two competing accounts of the DG superiority effect: Evans' (1989) positivity bias explanation, and Wharton, Cheng and Wickens' (1993) goal complementarity theory. The experiment independently manipulated the number of goals that participants had to explore (a single goal vs. two complementary goals) and the linguistic labels used to provide feedback (DAX and MED vs. 'fits the rule' and 'does not fit the rule'). Results supported the goal complementarity account in that facilitation was evident in both DG conditions irrespective of the polarity of the feedback provided. We also discuss a novel finding: that it is the production of at least a single 'negative' triple that is most closely associated with task success.

Introduction

Poletiek (2001) summarises hypothesis testing as comparing internal thoughts with external facts in order to interact with the world. For example learning a language can be characterised as hypotheses testing as the learner utters sounds and observes the listener's reactions. Hypothesis testing, therefore, can be viewed as a fundamental mode of mental functioning, and for this reason is of considerable interest to psychologists and cognitive scientists alike.

One important experimental paradigm that has been employed extensively in order to study hypothesis-testing behaviour is the 2-4-6 task, introduced by Peter Wason in 1960. The 2-4-6 task is a deceptively simple rule discovery task, which Wason originally devised to investigate whether people conformed to the

contemporary scientific norm of hypothesis testing, namely falsification (Popper, 1959). In the standard version of the 2-4-6 task, participants seek to discover a rule which generates sequences of three numbers (referred to as *triples*). They are initially given an example, conforming triple (2-4-6), and are then required to produce further triples which the experimenter classifies as either conforming to, or not conforming to, the rule. The to-be-discovered rule is 'any ascending sequence'. Participants produce triples until they are confident that they know the rule, at which point they announce it. Despite the seeming simplicity of the task, participants perform poorly, with typically only around 20% correctly announcing the rule on the first attempt, (e.g., Tukey, 1986; Wason, 1960; Wharton, Cheng & Wickens, 1993). Many of these incorrect announcements are a more restricted version of the rule, for example, 'numbers increasing by two'. It has been suggested (e.g., Wetherick, 1962) that the initial 2-4-6 exemplar lures participants into formulating such overly-restricted hypotheses. Participants then produce triples motivated by these hypotheses (e.g., 8-10-12), which always receive positive feedback, since they form a subset of the target rule. Faced with repeated confirmations of their hypothesis, participants seemingly become increasingly confident of its correctness until they announce it as the rule. It is clear that unless participants change their testing strategy they will never discover that although their hypothesis is sufficient, it is not necessary.

In his analysis of participants' performance on the task, Wason showed that solvers and non-solvers could be differentiated in terms of both the number of triples they produced (with solvers producing reliably more triples), and the type of triples generated (with solvers producing a higher proportion of triples which received negative feedback). Wason viewed the non-solvers' strategy of testing positive instances of their hypothesised rule as a cognitive failing, which he labeled 'confirmation bias'. However, Klayman and Ha (1987), in an elegant conceptual analysis of the underlying structure of the 2-4-6 task and its variants,

demonstrated that it is the *relationship* of the hypothesised rule to the target rule in the original task which causes participants' failure to discover the target rule. Klayman and Ha argue that what Wason regarded as a bias to seek confirmatory evidence could instead be conceptualised as a 'positive test strategy', which in certain circumstances is an effective method for yielding disconfirmations of a current hypothesis. Their essential point (cf. Wetherick's, 1962, argument noted earlier) is that in the standard task, the target rule ('any ascending sequence') has been deliberately designed to be more general than the hypothesis invited by the given triple, such that the application of a positive test strategy can never lead to the discovery of the target rule. For other target rule/hypothesis relationships, however, such as where the experimenter's rule (e.g., 'even numbers ascending by two and less than 10') is more restricted than the participant's initial hypothesis (e.g., 'numbers increasing by two'), then the implementation of positive testing would lead rapidly to falsification of the overly general initial hypothesis, and to accurate rule discovery.

Dual Goal Instructions

Tweney, Doherty, Wornor, Pliske, Mynatt, Gross, and Arrkellin (1980) introduced a modified form of the task, in which participants were instructed to discover two rules, one called DAX, the other MED. The DAX rule governs triples of the traditional ascending type, all other triples are MEDs. Although formally equivalent to Wason's original task, this simple Dual Goal (DG) manipulation was seen to have a dramatic effect on success rates, with 60% of participants making a correct first announcement of the rule. This facilitated performance has been shown to be a robust finding that has been replicated many times (e.g., Farris & Revlin, 1989a, 1989b; Tukey, 1986; Wharton, Cheng & Wickens, 1993). Tweney et al., were at a loss to explain the facilitatory effect of the DG manipulation, although they felt that the explanation was somehow related to the way participants conceptualise the task, and how triples produced are related to their conceptualisation.

It has been noted that the DG manipulation has the effect of increasing the *number* of triples which are generated before rule announcement, and also the *variety* of triples (Gorman, Stafford & Gorman, 1987; Tukey, 1986; Tweney et al., 1980). Vallée-Tourangeau, Austin and Rankin (1995), in their replication and extension of DG instructional effects, formulated two measures of triple heterogeneity, namely *posvars* and *negtypes*. Posvars are triples which receive positive feedback but which do not increase by a constant. Thus, if the numbers that make up a triple are *a*, *b*, and *c*, a posvar is a triple in which $(b-a) = (c-b)$. Negtypes are the eight possible types of triples which receive negative feedback, (e.g., descending triples, identical-

number triples, etc.). Vallée-Tourangeau et al. found that using these indices of triple heterogeneity, the DG manipulation led to increased production of both posvars and negtypes compared to Single Goal (SG) instructions. They interpreted this as being indicative of participants considering a wider range of hypotheses, although they did not directly test this claim. Whilst these observations of triple heterogeneity are interesting, they are largely descriptive, and do little to explain the facilitatory effect of DG instructions.

Evans (1989) proposed that poor performance on the standard task could be attributed to the operation of a general 'positivity bias', which is a form of selective processing that causes people to attend to positive rather than negative information. According to this proposal, facilitated performance using DG instructions is caused by the labeling of triples that 'do not fit the target rule' as MED, thereby avoiding a negative label, and hence counteracting participants' tendencies not to attend to this information. Evans (1989) argues that in the standard version of the 2-4-6 task, if a participant forms the hypothesis 'numbers ascending by equal intervals is right', they have logically also formed the hypothesis 'numbers not ascending by equal intervals is wrong'. They are, however, not aware of this alternative hypothesis, and therefore do not test it. In the DG manipulation, however, because participants are attempting to discover two rules, they test both DAX (correct) triples, and MED (incorrect) triples. Participants are more successful with the DG instructions since by carrying out positive tests of their MED hypotheses they are effectively carrying out negative tests of their DAX hypotheses, thus eliminating the overly restrictive hypotheses typically announced by the SG non-solvers. In summary, then, Evans argues that DG instructions facilitate performance by changing participants' representation of the task by creating a positive label for the previously negative 'does not fit' feedback.

Wharton et al. (1993) proposed a subtly different mechanism by which DG instructions improve performance. They invoke Klayman and Ha's (1987) proposal that a central feature of hypothesis testing behaviour is a tendency for individuals to adopt a positive test strategy which leads to the generation of triples that match their hypothesised rule. As we noted earlier, in the standard 2-4-6 task positive testing will never enable participants to discover the overly restrictive nature of their hypothesis as they will never generate a triple which lies outside of their hypothesis yet is still within the experimenter's target rule. With DG instructions, however, even though the exemplar triple for DAX suggests the same restricted hypothesis, the requirement to discover the second (MED) rule should encourage participants to form a second hypothesis (e.g., 'numbers ascending by intervals other

than two' are MED). On carrying out a positive test of the MED hypothesis, (e.g., 5-10-15) participants will (unexpectedly) receive DAX feedback, thus causing them to alter both their DAX and MED hypotheses. This sequence of events is repeated until satisfactory rules for DAX and MED are discovered. Thus, according to Wharton et al., it is the *complementary* nature of the two rules that leads to task success.

It is clear that Evans' (1989) positivity-bias account and Wharton et al.'s (1993) goal-complementarity account make very different predictions regarding performance on the 2-4-6 task. Evans' theory predicts that participants given positively-labeled DAX and MED feedback in relation to generated triples will perform better than those given a combination of 'fits the rule' (positively labeled) and 'does not fit the rule' (negatively labeled) feedback, and that this dissociation will be present irrespective of whether participants are asked to discover a single target rule or two complementary rules. In contrast, the goal-complementarity account proposed by Wharton et al. predicts that participants given the task of discovering two complementary rules will be more successful than those seeking a single rule, regardless of whether feedback is given as DAX/MED or 'fits'/'does not fit'. Previous studies of the facilitatory effect of DG instructions have always confounded these two variables, such that participants given DG instructions have always been given DAX/MED feedback, whilst those given SG instructions have always received 'fits'/'does not fit' or 'yes'/'no' feedback. The present experiment was designed to discriminate between the positivity-bias account and the goal complementarity theory, by manipulating these two factors independently. To this end, the participant's goal (i.e., discovery of one rule vs. discovery of two complementary rules) was systematically crossed with the linguistic label of the feedback (i.e., DAX/MED vs. 'fits the rule'/'does not fit the rule').

Method

Participants

Sixty undergraduates of varying backgrounds and ethnicity from the University of Derby took part in the experiment in exchange for course credits. They had not received any teaching on the psychology of reasoning before the experiment.

Design

A fully between participants design was employed that manipulated two factors: Goal (Single Goal vs. Dual Goal), and Linguistic Labeling (DAX/MED vs. Fits/Does Not Fit). Fifteen participants were randomly assigned to each of the four resulting conditions.

Procedure

Participants were tested in groups of up to four in a quiet laboratory. Standardised instructions were read to each group. Single Goal (SG) instructions referred to a unique rule: *'I have in mind a rule that specifies how to make up sequences of three numbers (triples), and your task is to discover this rule'*. In what we subsequently refer to as the SG—Fits condition, participants were asked to discover the target rule by generating triples which they would be told either 'fitted' or 'did not fit' the rule that the experimenter had in mind. On the other hand, in what we refer to as the SG—DAX condition, participants were told that triples that fitted the rule were called DAX triples and those that did not fit the rule were called MED triples. It was explained to participants that on generating a triple they would be informed as to whether it was a DAX or a MED triple.

The Dual Goal (DG) instructions emphasised that there were two rules to be discovered: *'...your task is to discover this rule, and also a second rule for categorising the triples that do not fit my rule'*. In the standard DG task (i.e., DG—DAX), participants were additionally informed that triples that fitted the rule were called DAX triples and those that did not fit the rule were called MED triples. They were instructed to produce further triples, which the experimenter would describe as either DAX or MED. In the DG—Fits condition, participants were told to generate triples which the experimenter would classify in terms of whether they 'fitted' or 'did not fit' the rule.

Participants in all conditions were given 2-4-6 as the example triple. All participants were provided with an answer sheet and were asked to write 2-4-6 on the first row, and either 'fits' or DAX in the feedback column, as appropriate. They were instructed that they could produce as many triples as they wished, and that when they were sure of the rule(s) they should write it (or them) on the answer sheet. In line with Gorman (1992), participants were allowed only one guess at the rule(s).

Results

Success Table 1 shows the frequency of correct and incorrect announcements by participants in each of the four experimental conditions.

Table 1: Frequency of correct announcements by condition.

Condition	N	Solvers	Non-Solvers
SG—DAX	15	3	12
SG—Fits	15	3	12
DG—DAX	15	12	3
DG—Fits	15	11	4

Table 2: Mean number of triples (and type of triples) produced by condition.

Condition	Total Triples	Posvars	Feedback	Negtypes
SG—DAX	7.6 (6.25)	0.33 (0.62)	0.73 (1.28)	0.33 (0.62)
SG—Fits	5.87 (2.75)	0.53 (1.36)	0.93 (1.58)	0.80 (1.42)
DG—DAX	10.27 (6.30)	1.13 (1.06)	2.67 (1.95)	1.20 (0.86)
DG—Fits	8.33 (3.22)	1.07 (1.10)	1.4 (1.24)	0.93 (0.80)

Note: SD in parenthesis.

Labeling of feedback (DAX/MED vs. Fits/Does Not Fit) seems to have had little effect on the likelihood of success; the proportions of solvers were similar between both the two SG groups and also the two DG groups. However more than three times the number of participants in the DG conditions than in the SG conditions announced the correct rule. A contingency table chi-square analysis was performed on the frequencies of correct and incorrect announcements (pooled over the labeling of feedback), and revealed a highly significant effect of the SG versus DG manipulation, $\chi^2(1) = 19.288$, $p < .001$.

Feedback Analyses were also performed to ascertain whether the manipulated factors had any effect on the type or number of triples produced (see Table 2). Again, the labeling of the feedback appeared to make little difference to the number or type of triples produced by participants. With regard to the SG versus DG instructions, however, there were significant main effects on three of the measures: number of triples produced, $F(1, 56) = 4.09$, $p < .05$; number of triples receiving negative feedback, $F(1, 56) = 9.1$, $p < .01$; and number of variable positive triples, $F(1, 56) = 5.86$, $p < .05$. The difference in the number of negtypes produced across SG and DG conditions also approached significance, $F(1, 56) = 3.96$, $p = .052$. There were no significant interactions for any of the measures.

Presence of Triple Types Although the analyses of triple type are interesting they do not give insight into the absolute importance of the production of the triple types. For this reason, it was decided to carry out further analyses in which the production of either a posvar or a negative triple was crossed with success on the task. In this way it would be possible to test whether the production of such triples is necessary for task success.

Table 3: Frequency of correct announcements by production of at least one posvar.

	Solvers	Non-Solvers	Total
Posvar produced	25	10	35
No Posvar produced	6	19	25
Total	31	29	60

A contingency table was, therefore, produced in which the production of *at least one* posvar was crossed with success (see Table 3). The table clearly demonstrates that the production of a single posvar is associated with success on the task, with four times the number of participants who produced a posvar making a correct announcement compared to those who did not produce one. A chi-square analysis confirmed the reliability of this observation, $\chi^2(1) = 13.137$, $p < .001$.

Table 4 shows a contingency table in which the production of at least one negative triple is crossed with success. Here the association is even more marked than in the case of the production of at least a single posvar, with there being only one instance of a participant who had not produced a negative triple correctly announcing the rule. In contrast, of the 34 participants who did produce a negative triple, 28 solved the task. A chi-square analysis revealed that these differences were highly significant, $\chi^2(1) = 36.363$, $p < .001$.

Table 4: Frequency of correct and incorrect announcements by production of a negative triple.

	Solvers	Non-Solvers	Total
Negative triple present	28	6	34
Negative triple absent	1	25	26
Total	29	29	60

Discussion

The results of the present experiment clearly support the goal complementarity account (Wharton et al., 1993) of the facilitatory effect of DG instructions on the 2-4-6 task. Evans' (1989) positivity-bias account, on the other hand, fails to find support in the evidence presented. The results show that DG superiority cannot be attributed to the re-labeling of negatively valenced 'does not fit' feedback as positive 'MED' feedback, as participants in the DG conditions performed significantly better than participants in the SG conditions, regardless of the nature of their feedback. This leads to the conclusion that the typically poor success rates on the standard form of the task cannot be accounted for by participants selectively attending to

positive information and thus ignoring a potentially informative set of triples. In relation to this point, the analyses of triple type and triple production show that participants in the DG condition produced a greater number and variety of triples. It could, therefore, be argued that it is not that SG instructions lead to selective processing of negative information, but rather that SG instructions do not promote the exploration of negative information in the first place (cf. Wharton et al., 1993).

The final set of analyses also revealed a hitherto unremarked phenomenon. It has long been noted that people who solve the 2-4-6 task tend to produce more triples as well as a greater proportion of negative triples (Wason, 1960). It has also been demonstrated more recently that solvers generate a greater variety of triples (e.g., Vallée-Tourangeau et al., 1995). What has not previously been shown, however, is that it is the production of at least a *single* negative triple that is so closely associated with success on the task. Indeed it remains possible that other indices of success such as the total number of triples produced or overall triple variety may well be mediating factors through which the critical negative triple is produced as a result of task manipulations. This is an area which would seem to require closer investigation.

The basic observation that negative-triple production is so closely related to task success, does, at first sight, appear rather paradoxical. The point is, that given the typically overly-restrictive hypotheses which participants form, it seems intuitively obvious that it should be the production of the discriminatory *posvars* (rather than negative triples) that would be most strongly associated with task success. Although our results do indicate that *posvar* generation is significantly linked to correct initial rule announcements on the task, it remains striking that the production of negative triples is even more predictive of task success. Why might this be the case?

One possibility is that the production of a *descending* triple (and its associated MED or 'does not fit' feedback) somehow makes the general dimension of *ascending numbers* appear to be relevant to the target DAX or 'fits' rule. The concept 'descending' may have this effect by facilitating the establishment of a salient contrast class that promotes an insight into the potential scope of the target rule. Closer investigation of the precise role of negative triples in facilitating task success - perhaps through the invocation of clear contrast sets within the space of possible triples - would, therefore, appear to be essential. To achieve this a finer-grained system of codifying the triples that participants produce may be required.

In summary, the results of this study clearly support a goal complementarity account of facilitated performance using DG instructions on the 2-4-6 task. Participants in the DG conditions were more successful at the task than those in the SG conditions. The lack of

effect with regard to the labeling of feedback would appear to undermine a standard positivity-bias account. Further work, however, is vital to understand the role that negative triples play in determining task success.

Abstract

A connectionist model for emergent planning behavior is proposed. The model demonstrates that a simple planning schema, acting in concert with two general purpose cognitive functionalities, namely, episodic memory and perception, can solve a restricted class of planning problems by backchaining from the goal to the current state. In spite of its simple structure, the schema can search for and execute plans involving multiple steps. We discuss how this simple model can be extended into a more powerful and expressive planning system by incorporating additional control and memory structures.

Introduction

Consider a classical planning problem, specified by an initial state, a goal state and a set of operators. A direct approach to solving this problem consists of searching the state space to find a 'path' between the initial and final states. Several symbolic planning systems adopting this approach in conjunction with the use of heuristics (Hoffman & Nebel, 2001; Haslum & Geffner, 2000; Bacchus & Teh, 1998) have recently shown notable improvements in efficiency on various benchmark problems.

Although a state space search algorithm is conceptually simple, it is not obvious how the data structures and control mechanisms required for the specification and execution of such an algorithm can be realized in a neurally plausible manner. In this paper we propose a connectionist model that exhibits a state-space search behavior. The model uses only a few simple control structures in conjunction with essential cognitive faculties, such as episodic memory, semantic memory, and perception.

Episodic memory (Tulving, 1995) refers to our ability to remember specific events and situations in our daily lives. The use of memory and experience in planning and reasoning has been investigated by several researchers (see (Waltz, 1995; Spalazzi, 2001) for useful accounts). Neurological and psychological data strongly suggests that episodic memory is distinct both in its functional characteristics and neural basis from other forms of memories such as semantic memory, memory for common sense knowledge, and procedural knowledge. It has been argued that events and situations in episodic memory are best viewed as *relational instances* that specify a set of bindings between the roles of a relational schema and objects that fill these roles in a given

event or situation (Shastri, 2001b; 2002). We assume that a planning agent is capable of remembering past events such as "performing action *A* under conditions *P* lead to consequences *C*". Each episodic memory trace of this type can be represented as a triple of the form *Preconditions, Action, Consequences*, and we will refer to such triples as PAC memories (or events)¹.

Finally, we assume that the planning agent is capable of observing the current world state through perception. By this we mean that the agent can determine whether or not certain perceptually salient and directly observable relations hold in the world. For example, in the context of the classical blocks world scenario, this assumes that the agent can look at the table and determine whether or not a specific block is 'clear.'

A memory-based planning schema

Figure 1 shows the abstract structure of the proposed planning schema. In order to explain its behavior, let us describe the functionality of each of its components and their interactions using a simple example.

Figure 1: A block diagram showing the basic components of the planning mechanism.

Consider a planning problem with only two blocks ('A' and 'B') where the agent's goal *G* is to achieve *On(A, B)* (i.e. block A on block B) and the current world state is *On(B, A)*. Let us assume that the agent's episodic memory contains the two PAC events *E*₁ and *E*₂:

¹Note that preconditions and consequences may contain multiple predicates.

- E₁) In state $P_1 = \{ \text{On}(B, A) \}$,
 action $A_1 = \text{Unstack}(B, A)$
 led to $C_1 = \{ \text{OnTable}(A), \text{OnTable}(B) \}$;
 E₂) In state $P_2 = \{ \text{OnTable}(A), \text{OnTable}(B) \}$,
 action $A_2 = \text{Stack}(A, B)$
 led to $C_2 = \{ \text{On}(A, B) \}$.

(1) Initialize

The schema activity is initialized by conveying the goal G ($\equiv \text{On}(A, B)$ in our example) as input to CURRENT GOAL². In the absence of any incoming activity from COMPARE, CURRENT GOAL simply passes control along with the goal (subgoal_{*i*} = G) to the RECALL component. The behavior of the CURRENT GOAL component in the presence of an input from COMPARE is different, and is described below.

(2) Recall

RECALL is activated when it receives the subgoal_{*i*} ($\text{On}(A, B)$, in the example) as input from CURRENT GOAL. The function of this component is to search episodic memory for an event wherein a specific *action* (say, A) performed under some specific *preconditions* (say, P) lead to a set of *consequences* (say, C) in which subgoal_{*i*} is true. In our example, E₂ happens to be such an event. When a matching event is found, action A and preconditions P are recollected and become 'active'; P becomes the current focus of the agent's attention³, and control is transferred to COMPARE, along with P as the current subgoal_{*i+1*}. In the example, subgoal_{*i+1*} = $P_2 = \{ \text{OnTable}(A), \text{OnTable}(B) \}$. If there are no events whose consequences 'match' the subgoal_{*i*}, the schema execution halts and signals a *failure*.

(3) Compare

The COMPARE block compares subgoal_{*i+1*} with the current world state, which is assumed to be observable through perception. It returns a positive outcome *iff* subgoal_{*i+1*} is true in the current state. In the example, the response is negative, as the world is still $\text{On}(B, A)$. After the comparison, the outcome and the subgoal_{*i+1*} ($=P$) are passed to CURRENT GOAL, which takes control of the activity and reacts as explained below.

(4) Repeat

If CURRENT GOAL receives a negative result from COMPARE, the following happens:

- the original goal G is no longer passed as input to RECALL, and ceases driving the activity of the schema;
- the set of preconditions P ($=$ subgoal_{*i+1*}) becomes the new subgoal_{*i*} and is passed to RECALL by the CURRENT GOAL component.

²It is assumed that this goal is represented in other networks outside the planning schema and communicated to the schema via controlled spreading activation.

³In order to achieve the original goal G , it suffices to achieve P and execute action A .

At this point, one loop is completed and the procedure repeats from step (2) with P as the current goal.

If CURRENT GOAL receives a positive input from COMPARE, the schema terminates returning *Success* and the control is given to an appropriate 'Action schema' that will carry out the action currently active in memory (A). If the original goal G is not achieved via the execution of this action, the planning schema is re-invoked and re-initialized with G . Note that we are not assuming the existence of a working memory which would allow the agent to dynamically store sub-goals during the planning process or to maintain active more than *one* PAC event at a time. Because of this, the proposed system is forced to 're-discover' parts of the same plan every time an action is executed, as described below.

Returning to the example, the result of COMPARE is negative and no action is performed: G is 'forgotten', while P_2 becomes the new subgoal_{*i*} and is passed on to RECALL. The schema now queries the episodic memory by asking if $\{ \text{OnTable}(A), \text{OnTable}(B) \}$ has been achieved in the past: PAC event E₁ is recollected. The precondition $P_1 = \{ \text{On}(B, A) \}$ – required to perform $\text{Unstack}(B, A)$ – becomes the new focus of attention and is compared with the current world state, producing a successful outcome: a chain of (two) PAC events connecting the goal to the initial state has been found, and the planning problem has been (potentially) solved. However, because of the absence of a working memory able to dynamically store goals and subgoals, all the agent can 'see' at this point is the last PAC event recollected. The currently active action ($A_1 = \text{Unstack}(B, A)$), though, can and *should* be executed, since this will get the current state one step closer to the goal. After the positive outcome of COMPARE, the schema terminates returning 'Success': the agent carries out the currently active action $\text{Unstack}(B, A)$, and the new state of the world becomes $\{ \text{OnTable}(A), \text{OnTable}(B) \}$.

After the action has been completed, the agent is 're-exposed' to the initial goal G (which has not been achieved yet), and the planning schema is re-invoked. The subsequent flow of activity is identical to the first part of the previous one, except that now $P_2 = \{ \text{OnTable}(A), \text{OnTable}(B) \}$ matches the current state of the world, and thus action $A_2 = \text{Stack}(A, B)$ is executed. This leads to achieving the original goal G , and the schema is no longer invoked.

The connectionist planning schema

The planning mechanism described above has been implemented using the representational machinery of SHRUTI, a neurally plausible structured connectionist architecture that demonstrates how a network of neuron-like elements can encode a large body of structured knowledge and perform a variety of inferences within a few hundred milliseconds (Shastri & Ajjanagadde, 1993; Shastri, 1999; Shastri & Wendelken, 2000).

SHRUTI suggests that the encoding of relational information (frames, predicates, and schemas) is mediated by

In the past, SHRUTI's representational machinery has been used to encode commonsense knowledge (Shastri & Ajjanagadde, 1993), causal models (Shastri & Wendelken, 2000), as well as action schemas and reactive plans (Shastri, Grannes, Narayanan & Feldman, 1997) and decision-making (Wendelken, 2001).

Consider the network structure depicted in Figure 2. This network fragment consists of two 'control' focal-clusters *ACHIEVE* and *RECALL*, two predicate focal-clusters *On* and *OnTable*, an action focal-cluster *Unstack*, two entity focal-clusters *A* and *B*, and a type focal-cluster *Block*. Typically, a focal-cluster contains several *control* and *role* nodes. For example, the focal-cluster *ACHIEVE* contains control nodes +, -, and ?, and role nodes *I* and *G* (the entity and type focal-clusters do not contain role nodes).

The *enabler* (?) node associated with a focal-cluster may be viewed as an "initiate query" or "initiate activity" node. In contrast, *collector* nodes (+ and -) associated with a focal-cluster indicate the outcome of a query or of other activity pertaining to the focal-cluster. In particular, the activation of the + (-) collector indicates a positive (negative) response to a query or signals a successful (unsuccessful) completion of some activity.

A query is communicated to a focal-cluster by activating its enabler node and binding its role nodes to appropriate role fillers. In Figure 2, the query "Can block B be placed on the table, given that B is on A?" is communicated by activating ? :ACHIEVE, and synchronizing the firing of ACHIEVE.I and +:On; the firing of ACHIEVE.G and +:OnTable; the firing of On.x, OnTable.x and ? :B; and that of On.y and ? :A. The activity of ACHIEVE propagates to the RECALL cluster, resulting in the query "Is there some action which led to

The diagram illustrates a hierarchical goal structure for a block stacking problem. At the top is the 'Block' goal, which branches into 'A' and 'B' goals. These goals further branch into 'OnTable(A)' and 'OnTable(B)' goals, which then branch into 'On(B,A)' and 'Unstack(x,y)' goals. The 'Unstack(x,y)' goal branches into 'Recall' and 'Achieve' goals. The 'Recall' goal branches into 'P', 'A', and 'C' goals. The 'Achieve' goal branches into 'I' and 'G' goals. The diagram uses various symbols (circles, squares, diamonds) to represent different types of goals and actions, and arrows to show the flow of the goal structure.

Fact structures attached to a relational focal-cluster encode specific instances of that relation. If the query active at a focal-cluster matches an attached fact, the fact becomes active and, in turn, activates the positive collector of the relation's focal-cluster, binding (via synchronous firing) each of the relation's role nodes to the entity filling these roles in the fact. A neurally plausible model of how this might happen in the brain is described in (Shastri, 2001b).

347

calls that performing $\text{Unstack}(B, A)$ when $\text{On}(B, A)$ was true lead to $\text{OnTable}(B)$ being true.

An important feature of the system consists of its ability to treat a relational instance as a role-filler (e.g. $\text{ACHIEVE}.I \equiv \text{On}(B, A)$). In order to support this requirement, SHRUTI allows for two levels of temporal synchrony. Bindings between standard role nodes and entity/type nodes are represented within a rapid *minor* oscillatory cycle, while bindings between specialized role nodes and relational instances are encoded within a slower *major* oscillatory cycle.

The simple schema described above, consisting of the ACHIEVE and RECALL clusters acting in concert with the episodic memory, can retrieve previously memorized 'if-then' (PAC) tuples. Thus, this schema can be construed as a *proto-planner* capable of returning one-step 'plans.' The next section demonstrates how this schema can search for *sequences* of actions, therefore constituting the next 'stage of evolution' of this proto-planner.

The planning schema in SHRUTI

Figure 3 shows how the planning schema of Figure 1 has been implemented using SHRUTI's representational machinery. It is easy to see how the focal clusters of this schema can be mapped to the elements of Figure 1 (the CURRENT GOAL block has been realized with two clusters, PLAN and SUBGOAL). We shall use the same example adopted earlier to illustrate how the schema can perform a basic form of *planning as search*.

Let us assume that the memory of the agent (represented only abstractly in the figure) contains the two PAC events of the previous example, namely, $E_1 = (P_1, A_1, C_1)$ and $E_2 = (P_2, A_2, C_2)$, and that the PERCEPTION block, when queried with input P, activates the + or - collector depending on whether the event bound to P is true or false in the observed world state.

The schema is invoked by activating the PLAN cluster's enabler ('?') node and by binding its role node G to the relational instance expressing the current goal ($\text{On}(A, B)$ in the example). After initialization, activity propagates upwards along links to clusters SUBGOAL and RECALL. After few major cycles, ? : RECALL is activated, with role C firing in synchrony with the current goal $\{\text{On}(A, B)\}$. The PAC event E_2 matches the activity in the cluster and is retrieved. Consequently, + : RECALL becomes active, and the roles A and P are instantiated with actions $A_2 = \text{Stack}(A, B)$ and relational instance $P_2 = \{\text{OnTable}(A, B)\}$, respectively (the clusters corresponding to predicate 'OnTable' and action 'Stack' are not shown in the figure). The activity of P reaches COMPARE. Since $\text{OnTable}(A, B)$ is not true in the current world state, - : COMPARE becomes active. This leads to the inhibition of the links from PLAN to SUBGOAL, which blocks the propagation of the query $\text{PLAN}(\text{On}(A, B))$ through the schema. Simultaneously, activity from COMPARE reaches SUBGOAL: the role node G starts firing in synchrony with P, which was temporally bound to the relational instance $\{\text{OnTable}(A, B)\}$. Hence, this becomes the

new (sub)goal of the schema, and its focus of attention. Activity from ? : SUBGOAL reaches ? : RECALL again, while role node C starts firing in synchrony with G. This leads to the retrieval of PAC event E_1 , and hence, the precondition $P_1 = \{\text{On}(A, B)\}$ gets bound to role P and role A is bound to the action instance $A_1 = \text{Unstack}(B, A)$. These bindings are in turn propagated to COMPARE.

Figure 3: A diagram showing the connectionist structure of the planning schema.

The positive outcome of the comparison leads to the activation of + : COMPARE, which communicates to PLAN that the search has terminated successfully. After action A_1 is executed, the initial goal $G = \{\text{On}(A, B)\}$ (not yet achieved and still present in the system) causes the schema to restart. The subsequent flow of activation is identical to the initial part of the previous sequence, except that when $P_2 = \{\text{OnTable}(A, B)\}$ is compared with the current state, the outcome is positive and the currently active action ($\text{Stack}(A, B)$) is executed. This achieves the goal G and terminates the activity.

Simulation results

The above planning schema has been realised and tested using the "SHRUTI Agent Simulator" software written in Java. The example described in the previous section has been used to test the functioning of the schema. Figure 4 shows the detailed trace of activation resulting from the actual simulation. Note how the diagram reflects closely the flow of activity described before, up to the first positive outcome of COMPARE.

Consider, for example, time point α of the diagram. Here, the PAC fact E_2 has just become active because of the initial query 'PLAN(On(A, B))', which has been propagated upwards and has led to the query 'RECALL(x, y, On(A, B))'. As a consequence,

the two preconditions {OnTable(A), OnTable(B)} are about to become active, and will be propagated to the COMPARE cluster, where they will be matched against the current state of the world⁴.

Figure 4: Node activation trace of the simulation.

Time point β is a snapshot of the situation immediately following the negative outcome of the (simulated) comparison. Notice how the flow of activity going from the PLAN cluster to the RECALL cluster has been interrupted by the negative outcome of COMPARE in order to allow the new goal {OnTable(A), OnTable(B)} to make its way through to cluster RECALL.

Discussion

The work described in this paper is part of a larger effort whose goal is to develop a neurally plausible architecture for reasoning, remembering, planning, and decision making. This paper presents progress along an important dimension of this ongoing effort. Perhaps the most interesting aspect of this work is the demonstration that general purpose cognitive faculties such as episodic memory, semantic memory and perception can be harnessed to produce a state-space search behavior and solve a subclass of planning problems.

The planning schema discussed in this paper is limited in a number of ways; however, as discussed below, this schema can be extended into a much more powerful and expressive planning system by incorporating additional control and memory structures, and by leveraging the full representational and expressive power of SHRUTI.

The proposed planning schema is susceptible to getting trapped in deadends. As the system searches for a

path from the goal to the initial state, it can get caught in a state that subsumes a set of conditions D which do not match the consequent of any PAC event in memory. There is, however, a simple three part solution to this problem. First, the agent detects that it has reached a deadend state (this is signaled by the activation of -:RECALL. Second, the agent memorizes that this path leads to a deadend in the context of the current problem. It can do so by memorizing the following episodic memory trace: iwhen trying to achieve the goal G , instantiating a subgoal D leads to a deadend. Third, the agent restarts the search and at each step in the search process retrieves both PAC and DEADEND events that match the current subgoal. Any retrieved PAC event that is counterindicated by retrieved DEADEND event is ignored. Since the memorization of deadends prunes the potential search space, with sufficient practice, the agent may memorize a large number of deadend events and carry out a highly efficient search.

Another limitation of the proposed planning schema is that it needs to traverse the same paths through the state space several times during the course of finding a plan. However, if the agent could remember the path traversed from the current goal to the initial state, it would not have to rediscover the same plan subsequences many times over: plan execution would involve traversing the memorized sequence of PAC events only once (in the reverse order) and executing the actions associated with each PAC event in the sequence. Note that remembering such a path can be viewed as memorizing a sequence of PAC events. Learning of event sequences is a well-known property of episodic memory, but it remains to be seen how the process of such on-line memorization of event sequences can be fully integrated with the on-line retrieval of previous episodic memories. Working memory mechanisms can also play a complementary role in such on-line memorization. Our current research addresses the functioning of episodic memory (Shastri, 2001b; 2002) as well as that of working memory, and we hope that the development of powerful episodic and working memory models will directly benefit future work in the development of planning schemas.

Since the proposed planning schema operates within the SHRUTI architecture, the full range of knowledge representation and reasoning capabilities of SHRUTI can be leveraged during planning. This includes representing and reasoning with commonsense (semantic) knowledge, causal models, type hierarchies, context-sensitive prior probabilities of events and estimated utility/value of world-states. Thus, general purpose domain knowledge as well as planning specific knowledge can be seamlessly combined to support planning involving not just memory retrieval, but also inference.

The functionality of the current planning schema is

⁴The perceptual task of verifying whether some conditions hold in the current world state was simulated by manually activating the + or - collector of the cluster eComparei as appropriate.

⁵The representational machinery required to encode such DEADEND events is similar to that required to encode PAC events: like PAC events, the episodic memory trace of DEADEND events also involves role-llers that are partial state-descriptions, specified by sets of conditions.

also limited by its inability to make use of goal decomposition. Imagine that the agent is trying to find a plan for the goal $G_1 \& G_2$ given the world state I and the two PAC events $PAC(I', a_1, G_1)$ and $PAC(I'', a_2, G_2)$ in memory. The planning schema described in this paper will be unable to solve the composite goal $G_1 \& G_2$, even though it will be able to solve each of the subgoals G_1 and G_2 if presented individually⁶. In order to deal with goal decomposition, the schema must (i) recognize that it can solve one of the subproblems using one of the PAC facts, (ii) pick the subproblem to be solved, (iii) note down the subproblem that it is deferring for now, (iv) find a solution to the selected subproblem, (v) shift attention back to the deferred subproblem, and (vi) solve the deferred subproblem. A connectionist implementation of this algorithm would require a more complex schema (control structure) than the one described in the previous sections, together with the ability to remember deferred goals. The memory of deferred goals can take the form of working memory (if deferred goals have to be remembered for a few seconds) or episodic memory (if the goals have to be remembered over longer time periods).

Another area of ongoing research of direct relevance to the work described here concerns the representation of complex action schemas and plans. In past work, we have shown that parameterized schemas capable of dealing with partially ordered actions, conditional actions, concurrent and iterative actions, as well as compositional and hierarchical actions can be encoded using SHRUTI's representational machinery (Shastri et al., 1997). This makes us confident that the more complex control structures required for encoding more sophisticated planning schemas would not present an insurmountable problem.

A key issue that remains open is the learning of appropriate control structures. We are investigating this question within the frameworks of spike-timing dependent synaptic plasticity (Wendelken & Shastri, 2000; Song, Miller & Abbott, 2000) and recruitment learning based on long-term potentiation (Malenka & Nicoll, 1999; Shastri, 2001a).

Abstract

Philosophers and linguists have claimed that verb meanings are divided into semantic types or superordinate categories that differ in internal conceptual structure. In particular, eventive verbs, which have internal causal structure are distinguished from stative verbs, which have no internal causal structure. In this paper, we explore the processing consequences of assuming that the lexical representations of verb meanings differ in the complexity of their internal representations. We conducted two experiments, a lexical decision task and a self-paced reading study, that investigated how verb types of different complexity are processed. We predicted that the conceptually more complex eventive verbs would take longer to process than stative verbs. In both experiments, this prediction was confirmed. This lends support to theories of verb concepts that propose classifications based on internal representations and shows that there are discrete and abstract conceptual categories in the domain of events.

Introduction

An important question in cognitive science concerns how word meanings (or lexical concepts) are internally represented. Although considerable progress has been made in the domain of nominal concepts since Rosch's studies, the nature and organization of verb concepts is less well understood. Early studies on verb meanings investigated whether verbs had internal semantic structure, as proposed in linguistic theories, but failed to find evidence supporting such a view (e.g., Fodor, Garrett, Walker, & Parkes 1980, Kintsch, 1974, Rayner & Duffy, 1986). For example, Rayner and Duffy (1986) measured the eye-fixation time on verbs during reading that were assumed to differ in internal complexity. They found no reading time differences corresponding to the semantic complexity of the verbs. This sort of finding, together with Fodor and colleagues' theoretical arguments (Fodor, 1975, Fodor, Fodor, & Garrett, 1975, Fodor & Lepore, 1998), was taken to support the view that verb meanings are atomic and lack internal structure. However, recent psycholinguistic studies challenge this view. Several sentence processing experiments have shown that lexical semantic properties such as selectional restrictions and verb-specific thematic roles (agent vs. patient) are quickly accessed by the processor when parsing syntactic ambiguities (e.g., Trueswell, Tanenhaus & Kello, 1993, Trueswell, Tanenhaus & Garnsey, 1994). More relevant to verb concepts per se, McRae, Ferretti & Amyote (1997) have shown that thematic roles have internal

conceptual structure (as object categories do) and that their feature structure is quickly accessed by the parser when resolving syntactic ambiguities. Moreover, Ferretti, McRae & Hatherell (2001) have shown that verbs prime their typical agents, patients and instruments (e.g., *praying* primes *nun*). They argue that verbs activate event schemas or generalized situation based knowledge that facilitate accessing the meaning of their typical participants. Finally, McKoon & Macfarland (2000) have found processing correlates of two types of verb meanings, those that are conceptualized as either externally caused events (e.g., *break*) or internally caused ones (e.g., *grow*). These verb types are assumed to differ in internal lexical complexity, particularly in their causal components (see also Gentner 1981). Taken together, these findings suggest that there is some internal structure in verb meanings: thematic structure and event types.

The work presented here further investigates verb concepts, i.e., how verbs, which refer to events, are processed and internally represented. In particular, we ask whether there are verb-general concepts and structures beyond and above the idiosyncratic meanings of individual verbs. We follow numerous linguistic and philosophical studies (as in McKoon & Macfarland, 2000) in assuming common structural and causal properties across classes of verbs that define superordinate concepts. Thus, beyond the existence of typical agent-verb-relations (that between *nuns* and *praying*), there may be more abstract structural or conceptual properties that organize our knowledge of events stored in the lexicon.

The classification of verbs and their semantic properties has been the topic of numerous philosophical and linguistic studies (Vendler, 1967). Following traditional Aristotelian classes, these studies have argued that there is a typology of events underlying verb uses. Verb types appear to be universal (Smith, 1991) and are supposed to reflect the way speakers conceptualize the domain of events, i.e., the semantic/conceptual properties they assign to a particular actual occurrence. One general distinction typically made between verb meanings is, among others, that between states and events (Vendler 1967, Dowty, 1979, Taylor 1977, Bach, 1986, Verkuyl, 1993, Jackendoff, 1990, Rappaport-Hovav & Levin 1998). The distinction seems cognitively basic because it is grounded in causal properties: eventive verbs typically denote a cause and a change from an initial state to a resulting one (e.g. *write*, *destroy*), while stative verbs simply denote properties or stable relations between participants (e.g. *love*, *belong*, *contain*) (Dowty, 1979, Parsons 1990). The

distinction presupposes that verb lexical meanings have internal conceptual structures that differ in complexity: event lexical concepts have internal sub-components derived from their causal properties (e.g., the cause and the resulting state), while states lack any such components.

In this paper, we investigate how verbs denoting states and events are processed and represented. In particular, we ask whether eventive and stative verbs, which drastically differ in their semantic-conceptual complexity, are processed in ways consistent with their complexity. Two psycholinguistic experiments show that speakers' processing of verb meanings varies according to lexical semantic complexity, thus supporting the view that eventive and stative verbs are represented differently.

The Distinction between Verb Classes

Eventive and stative verbs are distinguished by semantic and syntactic properties. Syntactically, they differ in their ability to co-occur with certain adverbs and in certain constructions. These distributional restrictions are taken as tests that identify membership in one verb class or another. For example, stative verbs such as *deserve* are distinguished by their ability to occur with simple present in English but not present progressive, as in (1) and (2). Similarly, stative verbs cannot occur in nominalized constructions such as that in (3), cannot appear as complements of verbs like *force* as in (4), and cannot be modified by adverbial phrases as in (5). In contrast, eventive verbs such as *build* have the opposite distributions (for more tests, see Dowty 1979):

- (1) Bill *is deserving** / *is building* something.
- (2) Bill *deserves* / *builds** something.
- (3) What Bill did was to *deserve** / *build* something.
- (4) Bill forced Mary to *deserve** / *build* something.
- (5) Bill *deserved** / *built* something in an hour.

The intuition behind (1)-(4) is that the participants of a stative eventuality are not causal or volitional agents. Rather, they are *experiencers*. The two classes thus involve different relations between their participants. The intuition behind (5) is that states persist in time while events have ending points or culminations. Examples of each verb type are given in Table 1.

Table 1: Verb examples

<i>Events</i>	<i>States</i>
enter	live
accuse	love
create	contain
give	know
build	despise
buy	constitute
betray	cherish

Semantically, the classes are distinguished by logical entailments. When each verb type occurs in sentences, they allow or disallow distinctive inference patterns. The entailments refer to causal and temporal properties of the construed eventuality as a whole. Stative sentences imply facts, i.e., they entail that they hold true for an indefinite period of time. In contrast, eventive verbs have the change-of-state entailment: they either entail a single change of state, as in (6) and (7) below (in Vendler's classification, achievement and accomplishment verbs), or sequence of changes as in (8) (activity verbs). These changes are caused by either an agent's single act or a series of actions that may be sustained for a while. But in contrast to states (which can persist on their own) events stop when their cause does so that they do not hold for indefinite periods.

- (6) x killed $y \rightarrow x$ caused y to become dead
- (7) x built $y \rightarrow x$ caused y to become existent
- (8) x hammered $y \rightarrow x$ caused y to become hammered

The temporal entailments distinguishing each class are the counterpart of their causal properties. Because states have no internal (causal) structure, they are true at a given interval as well as at any subpart of this interval. More precisely, if a state is true at any interval i , it follows that it is true at all instants within i , as in (9).

- (9) If Bill had a bike last week, he had a bike throughout the week.

This entailment is called temporal homogeneity. In contrast, events lack this property (Dowty 1979): if a change of state is true at any interval i , it follows that it is false at the initial part of i , (the initial state) and it is true at the final part of i (the final state) as in (10):

- (10) If Bill wrote a letter in an hour, the letter was not written before the hour and was written right after it.

The entailment captures the fact that single-change events typically have sub-parts (the initial and resulting state) so that the event as a whole cannot be true until it is completed. This also holds for activity events at the level of each component change. It follows that events are not temporally homogeneous because their truth at a given interval does not hold at any sub-instant.

It is clear that whether one focuses on their temporal or causal properties, states are fundamentally different from events. While states lack internal causal structure and are temporally homogeneous, events have complex causal structures and are not temporally homogeneous.

The contrast between these verb classes has led linguists to propose conceptual lexical representations that capture their semantic properties and the relations between their participants. The representations are expressed via logical operators (Dowty 1979) or primitive

predicates (Rappaport Hovav & Levin 1998, Jackendoff, 1990) such as CAUSE and BECOME, together with verb-specific lexical predicates that hold true of their arguments. Consider the representations of the following verbs:

write = *x* CAUSE(BECOME(*y* be-written))
break = *x* CAUSE(BECOME (*y* be-broken))
possess = *x* possess *y*
deserve = *x* deserve *y*

Because verbs of the same type have structurally similar representations, the distinction between events and states can be expressed in verb-general conceptual structures:

Events *x* CAUSE(BECOME(*y* state))
States *x* state *y* = state(*x*, *y*)

Eventive representations typically involve changes and causes, while stative representations simply involve a stative predicate that holds true of participants. In fact, stative predicates are component part of events, because changes include resultative states. This renders eventive verbs as semantically more complex than stative verbs.

Experimental Evidence

If the mental representations of verbs in fact differ due to their causal and temporal properties, this suggests that each verb type may involve differential processing cost depending on internal complexity. Representing the meaning of an eventive verb entails representing different alternative states of affairs such as the initial state and final state resulting from the agent's intervention. In contrast, representing the meaning of a stative verb implies representing a single state of affairs. If processing a verb implies accessing and processing its lexical meaning, more complex meanings should yield longer processing time. To test this empirical prediction, we conducted two psycholinguistic experiments. The first experiment was a visual lexical decision task. This task has been shown to be sensitive to top-down influences of meaning (see Balota, 1994, Balota, Ferraro & Connor, 1991) and several semantic effects such as abstract vs. concrete aspects of meaning have been reported (Blesdale, 1987, Eviatar, Menn & Zaidel, 1990, Paivio, 1991). The second experiment was a self-paced reading study, in which the reading time of verbs (occurring in sentences) was measured. Previous literature has shown that lexical complexity factors such as number of senses (Rayner & Duffy 1986) and type of verbs (McKoon & Macfarland 2000) have an effect on reading times.

Experiment 1: Visual Lexical Decision Task

In this experiment, we ask whether stative verbs are recognized faster than eventive verbs, given the hypothesized semantic complexity differences.

Materials 31 and 32 words were selected for each verb type (states and event) according to the semantic and syntactic criteria discussed in Dowty, 1979. The items were matched for word length, frequency (Associate Press Corpus, mean frequency for events = 2.40, and for states = 2.45), number of sense (WordNet database: events: 2.79; states: 2.59), number of orthographic neighbors (events: 2.23, states: 1.85) and argument structure. Verbs were transitive verbs (taking obligatory NP or PP complements), except for 6 intransitive verbs in each class, and were not ambiguous between noun and verb uses. Non-words (= 62) were possible words similar to real words. This favors deeper processing of words, because written form is not sufficient discriminator to perform the task (see Seidenberg, Petersen, MacDonald & Plaut, 1996).

In a pre-test study, imageability ratings (how easy is it to imagine/visualize the meaning of a word) were collected from another set of subjects to control for the possibility of this effect. We subsequently used the items' imageability ratings as a covariate in our analysis. The rationale for incorporating this factor derives from the observation that higher imageability ratings are associated with faster reaction times (James, 1975, Paivio, 1991, Strain, Patterson & Seidenberg, 1995). We used the instructions provided in Chiarello, Shears, & Lund's (1999) norming. Comparisons of these ratings across categories revealed that the categories differed, with eventive verbs being more imageable (mean for events = 4.21 in a scale from 1 to 7, mean for states = 3.25, $p = .001$).

Examples of test words are the following:

Events: betray, borrow, conquer, create, deduce, align, attract, devour.

States: adore, aspire, believe, belong, cherish, comprise, contain, deserve, detest.

Participants and Procedure 52 right-handed native speakers of English participated in this study, all students at the University of Maryland. For each word presented in the screen, participants decided whether it was a word of English. The experiment was carried out in G3 Macintosh computer running Psyscope. Words were presented at varying inter-trial time (500-1500 ms) on the center of the screen. Before each stimulus word or non-word, a fixation point was presented for 500 ms. The reaction time (RT) to each stimulus was automatically collected.

Results Analysis of covariance across items with RTs as dependent variable and imageability ratings as covariate revealed a significant main effect of imageability ($F(1,60) = 7.19$, $p = .009$), a main effect of word type ($F(1, 60) = 7.95$, $p = .006$) and no interaction. The overall word effect is represented in Figure 1, with bars representing standard error. Mean difference was small but reliable, (about 20 ms), because not all state/event pairs show big

differences. We also conducted an analysis across subjects with similar result ($F(51,1)=40.21, p=.0001$).

Figure 1: RTs as a function of word type

We interpret these findings as indicating that both imageability and meaning complexity have an effect on RTs. The lack of an interaction between the two main effects indicates that the word type effect does not depend on imageability. Overall these results support the prediction that stative verbs are recognized faster than eventive verbs, consistent with an effect of representational complexity.

Experiment 2: Self-paced Reading study

In this experiment, we asked whether stative verbs are processed faster than eventive verbs when integrated into previous information in the process of sentence comprehension. For this, we measured the reading time to verbs of the sentence stimuli.

Materials 84 sentences containing 42 stative and 42 eventive verbs (plus fillers) were selected. Test verbs and sentences were carefully matched for a number of variables known to affect reading times in context. First, the verbs were pair-wise matched for frequency and word length. Mean log-frequency for both states and events was 3.96 and the mean word length was 6.11 characters for events and 5.82 for states (Collins Cobuild corpus). Comparisons of these variables were not significant.

Second, we pair-wise matched the verbs used in the sentences by their number of syntactic arguments and preferred (most frequent) syntactic frames. This is because Shapiro, Nagel & Levine (1993), Shapiro, Zuriff, & Grimshaw (1987), Rayner and Duffy (1986), McElree (1993) and others have shown that argument structure complexity as well as preferred argument structure can have behavioral consequences in reading times. We used Schulte im Walde's (1999) electronic corpus based on syntactic analysis of the Bank of English to compute number of syntactic arguments and the frequency of syntactic frames. Each selected verb pair had roughly the

same number of syntactic frames in which they can occur and for the most frequent frame, the same number of arguments. For example, *love* was matched with *build*, which have similar log frequencies. Proportions of corpus occurrences in different syntactic frames is the following:

<i>love</i>		<i>build</i>	
subj:obj	0.67	subj:obj	0.76
subj:to-inf	0.10	subj:obj:obj	0.05
subj:v-ing	0.03	subj:obj:for	0.04

Both verbs occur very frequently in transitive uses, and both verbs have 3 possible argument structures. For verbs like *believe* (equi-biased verbs), which have two equally frequent argument structure (NP, sentence complement), the two most frequent frames were matched for number of arguments. So, *believe* was matched with *report*, which have roughly the same frequent syntactic frames.

Third, test sentences were exactly alike up to the point of the verb, and in some cases, the sentences were completely alike except for the verb. This eliminates the possibility that factors associated with preceding words affect the reading time of the verbs. Examples of matched verb and sentence stimuli are the following:

- (11) The young boy bullied his parents. (event)
The young boy adored his parents. (state)
- (12) The retired musician built a house. (event)
The retired musician loved his daughter. (state)

Finally, we control for the plausibility relation between the subject NP and the verb. Because certain types of subjects may be more likely to appear with one or the other verb type, we obtained individuals' judgments rating the typicality of the subject-verb relation. We asked 50 students to rate how typical it was for a given subject NP to perform the corresponding action denoted by the verb (Trueswell, et al. 1994). The ratings were compared across word types and did not differ significantly ($t<1$). The mean rating for events and states were 5.51 and 5.60 respectively in a scale of 1 to 7.

Procedure 30 students at University of Maryland read sentences on the computer screen. After each sentence, participants answered a comprehension question. The words of the sentences were presented one-by-one and the participants pressed a key on the keyboard to see each word. Reading time for each word was recorded, though our interest was in the reading time of verbs.

Results comparison of reading times at the verb position revealed a word type effect both across subjects ($F(1, 29)=10.66, p=.003$) and items ($F(1,43)=8.9, p=.004$). Eventive verbs took longer to process than state verb (about 25 ms. difference). Figure 2 represents the mean reading times (and standard errors) for the nouns preceding the verb, the verb position and the next word.

The results are thus similar to those of the lexical decision task and strongly support our hypothesis of a semantic complexity difference between verb meanings. Semantic complexity in this experiment is clearly independent of syntactic behavior and argument structure complexity.

Figure 2: Reading times as function of word type and position

Discussion

The results of these experiments show that eventive verbs take longer to process than stative ones, thus supporting the view that the mental representations associated with them differ in semantic complexity. Computing the verbs' meanings involves differential processing cost, as suggested by the hypothesized complexity of conceptual representations. The distinction between these verb classes is rather abstract and is based on whether the verbs involve a change of states. To our knowledge, this is the first time that these verb classes are shown to have empirical correlates.

Note that the results cannot be attributed to syntactic differences among verbs (frames or number of arguments), as this factor was kept constant. Nor can they be explained as a consequence of expectations generated by the type of arguments with which verbs occur, a factor that has been often manipulated in studies of syntactic ambiguity resolution. In our sentence comprehension experiment, the same subject-arguments were used for both eventive and stative verbs and the plausibility relations between subject-argument and verb were equalized. Also, no such factor was present in the lexical decision task. Thus, the alternative interpretation of the results in which there is a processing difference but not a representational one does not seem plausible, as there is no apparent reason to expect a purely processing difference. We are inclined to conclude, then, that difference in processing cost are due to representational complexity differences between states and events and that such differences may rely on the causal vs. non-causal relations they establish between their participants.

However, the results are neutral as to whether representations such as *x CAUSE(BECOME(y state))* are

accurate expressions of the internal representation of the verb meaning. These results only suggest that the representation of eventive verbs is more complex than that of stative ones, regardless of how the complexity is spelled out. Yet if the internal mental representation of verbs includes the type of relations that they establish between participants, it is possible that the complexity difference is due to causal features. In one case, the eventualities denoted involve changes and cause-effect relations (and therefore, agentive participants), while in the other case, they involve mere descriptions of facts. These are important cognitive differences that may somehow be abstracted over verb-specific meaning.

Our results have some important implications for theories of word meanings. As McKoon & Macfarland's (2000) findings, our results challenge the view that verb meanings are atomic and unstructured. On such a view, there is no principled reason to expect these differences in processing unless the lexical entry is allowed to have some sort of internal structure. In this respect, the failure of previous attempts to find lexical complexity effects could be due to the fact that indirect measures of complexity were used (e.g., Fodor et al. 1980) or very small (perhaps undetectable) differences between verb classes were investigated (e.g., Rayner & Duffy, 1986).

Our results also suggest that part of the information encoded in the verb is semantic/conceptual, and somewhat independent from number of participants and syntactic frames. Several psycholinguistic studies have shown that these syntactic variables do influence behavioral measures (e.g., Shapiro et al. 1993). Similarly, Fodor & Lepore (1998) claim that syntactic combinatorial rules can be part of lexical entries, thus increasing their complexity. Our results indicate however, that such syntactic information is not the only relevant factor for complexity effects. Purely semantic properties can also yield processing time differences.

Finally, our results have implication about the exact source of the semantic complexity effects and the overall organization of verb concepts in the lexicon. McRae et al. (1997) and Ferretti et al. (2001) have suggested that events in memory are organized in event schemas and that such schemas arise from the knowledge of their typical agents and patients acquired during learning, i.e., thematic feature knowledge. Thus, it is in principle possible that the verb classes studied here can be distinguished by such thematic features (e.g. features defining agent/patient vs. experiencer/entity structures). However, it is unclear how these features would explain the complexity effects. More importantly, it is unclear whether such features can in fact be distinguished from other aspects of the verb meaning such as the relation between participants established by the verb. Both types of information are inherently related. Our results suggest a level of abstraction or generalization of verb schemas that goes beyond verb-specific knowledge of typical participants and typical situations. Rather, as is the case for nominal concepts, verb concepts

seem to be organized in major event types, in this case distinguished by general causal properties. These types provide the domain of events with a hierarchical organizational structure from verb-specific concepts to abstract verb-general concepts.

Marina del Rey, CA 90292, USA

Abstract

This paper argues that interactive knowledge acquisition tools would benefit from a tighter and more thorough incorporation of tutoring and learning principles. Current systems learn from users in a very passive and disengaged manner, and could be designed to incorporate the proactive capabilities that one expects of a good student. This paper points out what tutoring and learning principles have been used to date in the acquisition literature, though unintentionally and implicitly. We discuss how a more thorough and explicit representation of these principles would help improve enormously how computers learn from users.

Introduction

Computers have long been considered an invaluable tool for education. Intelligent tutoring systems and other kinds of educational software show how people can acquire knowledge about diverse topics by interacting with a computer. Given our reliance in computers for the future of education, we need to realize that an important component of the human education revolution is the computer education revolution: anyone should be able to teach computers on topics that are of value, so that anyone can learn about those topics from computers. So an important question is: how will computers acquire knowledge? In most cases knowledge is entered by hand by software or knowledge engineers, as is often done in intelligent tutoring systems (Forbus & Feltovich, 2001). This limits severely the utility of the tools, as it would be more desirable that the people with expertise in the domain at hand would be the knowledge providers. Knowledge can also be extracted from text (Cowie & Lehnert, 1996), although given the error rates of state of the art systems and the kinds of knowledge they acquire (mostly instance-level information) it will take many years for these techniques to be of practical use to build an accurate body of knowledge about a topic domain. Another possibility is to use interactive knowledge acquisition tools that help users enter knowledge. In recent years these systems have shown that end users with no background in computer science or knowledge representation were able to enter sizeable amounts of knowledge (Kim & Gil, 1999; Eriksson et al, 1995; Clark et al, 2001).

Although interactive knowledge acquisition tools enable end users to enter knowledge, users remain largely responsible for the acquisition process, both the teaching side and the learning side. These tools are quite passive in terms of formulating or pursuing learning goals, keeping track of the flow of a lesson, and generally assess how much they are learning and how useful that knowledge is. At the same time, users are not necessarily skilled teachers by nature, so being in a position to teach a computer is already a challenge for them. Interactive acquisition tools need to be more effective and helpful to users, perhaps by incorporating some of the skills that are expected of good students. And, as good students do, they should also be able to cope with an inexperienced teacher (which their users are likely to be) and still learn from the experience by bringing to bear knowledge about how a good teacher typically goes about a lesson. An interactive acquisition tool could then be viewed as a tool to support augmented cognition, since it would supplement the user's limitations as a teacher and knowledge engineer.

The contributions of this work are twofold. First, we point out how existing knowledge acquisition tools use techniques that are related to widely used tutoring and learning principles. Second, we identify areas that the acquisition tools developed to date have neglected, and suggest promising areas of research based on our findings. This would result in a new generation of acquisition tools that are not only better students but also more helpful to the teacher (the user).

The paper begins with a short introduction and background on interactive knowledge acquisition tools. We then discuss several tutoring and learning principles that we have drawn from the educational literature and that seem useful to support the interactive acquisition process. Next, we show how some existing acquisition tools use techniques that are related to these principles in some aspects of their functionality. We finalize with a discussion of promising directions that we see in designing acquisition tools that incorporate tutoring and learning principles more thoroughly.

Acquisition Tool	Highlights
CHIMAERA (McGuinness et al., 2000)	To acquire concepts, relations, and instances. Diagnoses faulty definitions.
EXPECT (Blythe et al., 2001)	To acquire problem solving knowledge. Exploits dialogue scripts, knowledge interdependency models, and background knowledge.
INSTRUCTO-SOAR (Huffman & Laird 1995)	To acquire task models for Soar.
KSSn (Gaines & Shaw, 1993)	To acquire concepts, rules, and data. Based on personal construct psychology.
PROTOS (Porter et al., 1990)	Users specify cases, tool explains their classification.
SALT (Marcus, 1988)	To acquire constraints and fixes for its underlying engine for configuration design.
SEEK2 (Ginsberg, 1985)	To acquire rules. Uses verification and validation techniques.
SHAKEN (Clark et al., 2001)	To acquire process models. Loosely based on concept maps.
TAQL (Yost, 1993)	To acquire SOAR rules. Based on Problem Space Computational Model.
TEIREISIAS (Davis, 1979)	To acquire rules. Exploits context, derived rule models, and heuristics.

Table 1: Some Interactive Knowledge Acquisition Tools.

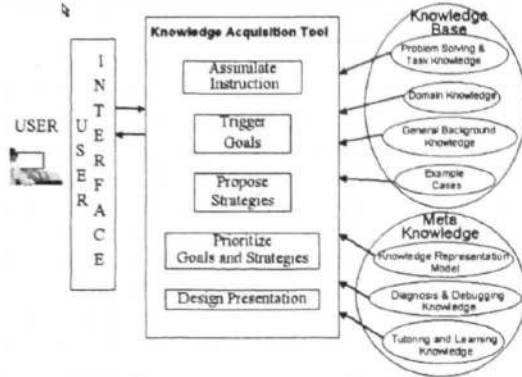

Figure 1: A Modular View of Interactive Knowledge Acquisition Tools.

Interactive Knowledge Acquisition Tools

The interactive knowledge acquisition tools summarized in Table 1 illustrate different approaches that researchers have undertaken over the years and are representative of the literature. A brief description of the tools are in Gil and Kim (2002). The techniques used range from cognitive theories of expertise and learning, case-based reasoning and analogy, non-monotonic theory revision, induction and machine learning, knowledge engineering approaches, analysis of knowledge interdependencies and buggy knowledge, and agent-based interaction.

Figure 1 shows a diagrammatic view of typical components used in various tools. The functionality of an interactive knowledge acquisition tool can be described along five dimensions, which we will use for reference later in our analysis:

- Assimilate instruction:** Given a user's instruction, the system makes the necessary additions or changes to the knowledge base and updates any other internal structures. Instruction may be given as an example (PROTOS, SEEK2), a natural language statement (INSTRUCTO-SOAR), a descriptive piece of knowledge (CHIMAERA, EXPECT, SALT, TAQL), or a graphical rendering (KSSn, SHAKEN).
- Trigger goals:** The system analyzes its knowledge and generates learning goals of what knowledge it still needs to acquire. Many tools focus on detecting inconsistencies or gaps in the knowledge base, which generate the goals to fix them or seek the information missing (CHIMAERA, EXPECT, SEEK2, TAQL, TEIREISIAS).
- Propose strategies:** The tool can generate possible strategies that the user could follow in achieving the learning goals. It can also generate predictions of what strategy the user is more likely to pursue, or what answers the user is more likely to give to the user's questions (TEIREISIAS). This is often done by analyzing existing knowledge. Planning strategies are often used to make suggestions to the user in terms of what to do to achieve the active learning goals, which will make the acquisition process more efficient (EXPECT).
- Prioritize goals and strategies:** An acquisition tool can help users further if it is able to organize and prioritize the active learning goals and candidate strategies, so that it can make more focused suggestions to the user. Sometimes these are organized by the type of knowledge sought (SALT), or by the type of goal being pursued or error being fixed (EXPECT).
- Design presentation:** The tool can make decisions about what to bring to the attention of the user at each point in time to help him or her decide what to do next. There are many possibilities, and the tool can take into account the user's situation (user modeling), the stage of the process (initial stage versus final testing), and the content of the current knowledge base. The tool may present the user with a single question (INSTRUCTO-SOAR) or give the user a choice in the form of an agenda containing multiple items (CHIMAERA, EXPECT, SALT). The tool can suggest a specific strategy, anticipate the user's answer and ask for confirmation, or simply present the user with multiple possible strategies and suggestions (EXPECT). Other tools leave it up to the user to figure out what to do and simply make all possible options available to them (KSSn,

SHAKEN) The tool may simply ask the user to review an explanation (PROTOS), check some aspect of the knowledge (KSSn), or confirm a hypothesis (TEIREISIAS).

Another useful view of interactive acquisition tools is in terms of the kinds of knowledge and meta-knowledge that they bring to bear in order to support the user, also illustrated in Figure 1. This includes:

- *General problem solving and task knowledge:* General inference structures are used to determine the role that domain-specific knowledge plays in problem solving, as is done in role-limiting approaches to knowledge acquisition (Marcus & McDermott, 1989) (e.g., SALT, TAQL).
- *Prior domain knowledge:* The initial knowledge base may contain terms that are specific to the domain at hand and that can be used to define new terms and tasks (e.g., EXPECT, INSTRUCTO-SOAR).
- *General background knowledge:* The initial knowledge base may include high level theories and ontologies that capture general knowledge, such as time, physical objects, etc. (e.g., SHAKEN).
- *Example cases:* Sample situations, test cases, and problem solving episodes can help ground abstract knowledge (e.g., INSTRUCTO-SOAR, PROTOS, SEEK2, SHAKEN, TEIREISIAS).
- *Underlying knowledge representation:* Models of the underlying knowledge representation will determine how users need to formulate new knowledge (e.g., CHIMAERA, KSSn, SEEK2, TAQL, TEIREISIAS).
- *Diagnosis and debugging knowledge:* Typical diagnosis skills are useful in order to detect errors and potential problems in the knowledge base. Effective debugging strategies can be incorporated to make suggestions to the user about how to fix the errors and problems found (e.g., CHIMAERA, EXPECT, TEIREISIAS).

One source of meta-knowledge that has not received attention is effective tutoring and learning techniques. By exploiting meta-knowledge about how to learn and how to teach, acquisition tools will become more proactive learners and will be able to help users teach them more effectively. Current tools are often too passive, and place on the user the majority of the burden of the acquisition process. Our goal is to understand whether and how knowledge acquisition tools can exploit knowledge about tutoring and learning.

Tutoring and Learning Principles in Existing Interactive Acquisition Tools

We analyzed the tutoring and educational literature to compile tutoring and learning principles that humans and computers exploit to make teaching and learning more effective. We compiled fifteen principles that could be of immediate use in our work, and that are described in detail in (Kim & Gil, 2002) including detailed references to the tutoring literature that are omitted in this paper because of space limitations.

We noticed that many of these principles could be related to the techniques used in existing acquisition tools. Yet, the tutoring literature is seldom mentioned in knowledge acquisition work. In this section, we describe our views on how acquisition techniques can be expressed in terms of these tutoring and learning principles. Table 2 summarizes our analysis, indicating the particular functionality (as outlined in Figure 1) where the principle was applied in specific acquisition tools.

Introduce lesson topics and goals

Teachers often start off by introducing the topics and goals of the lesson. There is no notion in acquisition tools that there is a lesson being started or ended, since at any point users can choose to enter knowledge about any topic. EXPECT allows users to specify the top-level tasks that the system should be able to solve with the new knowledge, which can be viewed as a statement of the goals for that acquisition session. SEEK2 has a suite of test cases that the system should be able to solve after the lesson, and that could be viewed as a statement of the goals of the lesson.

Use topics of the lesson as a guide

It is useful for students and tutors to ensure that what is being learned has some connection or relevance to the topics of the lesson. EXPECT uses the specified top-level tasks to check that any new knowledge specified solves some of their subtask, and if not it notifies the user and suggests how it could play a role in solving the tasks. SEEK2 uses the suite of test cases to detect errors, which then drive the dialogue with the user towards fixing them. SALT can be viewed as having an implicit (and very high level) topic for all sessions, namely to acquire knowledge for configuration design problems. SALT's interface asked users to specify only three kinds of knowledge (parameters, constraints, and fixes) that are relevant to those types of problems.

Subsumption to existing cognitive structure

Learning about a new topic involves relating the new knowledge to what is already known, for example by

Tutoring/Learning principle	Assimilate Instruction	Trigger Goals	Propose Strategies	Prioritize Goals and Strategies	Design Presentation
Introduce lesson topics and goals		EXPECT, SEEK2			
Use topics of the lesson as a guide	SALT	SEEK2	EXPECT		SALT
Subsumption to existing cognitive structure	PROTOS		TEIREISIAS		PROTOS, SALT
Immediate feedback	PROTOS	INSTRUCTO-SOAR	TEIREISIAS		EXPECT
Generate educated guesses		TEIREISIAS	EXPECT		
Keep on track					
Indicate lack of understanding	INSTRUCTO-SOAR				INSTRUCTO-SOAR
Detect and fix "buggy" knowledge	TAQL	EXPECT CHIMAERA			PROTOS, SEEK2 TEIREISIAS
Learn deep models					
Learn domain language					
Keep track of correct answers		SEEK2			
Prioritize learning tasks				EXPECT	
Summarize what was learned					
Assess learned knowledge		KSSn			

Table 2: Tutoring and learning principles used in acquisition tools.

checking inconsistencies, drawing analogies, or deriving generalizations. PROTOS took a new example case provided by the user, and indexes it into one of several classes (or categories) of examples. It also presented the user with an explanation of the classification of the new example to show how the new knowledge was incorporated into the existing structures. TEIREISIAS created generalized rule models from its rule base, and used them to propose to the user additional conditions to newly defined rules. The interface and presentation of SALT was always based on the kinds of knowledge needed for configuration design.

Immediate feedback

Educational systems often provide immediate feedback, as studies show that it is more effective than feedback received after a delay. PROTOS provided immediate feedback as a new case was assimilated by showing the user an explanation of its classification in the knowledge base. INSTRUCTO-SOAR generated clarification and follow-up questions for the user immediately after an instruction was given. TEIREISIAS proposed amendments to rules as soon as the user defined them. EXPECT analyzes the knowledge base after each user action and shows immediately an agenda of errors to resolve and tasks to do.

Generate educated guesses

Students often show their understanding by finishing a tutor's utterance, and tutors often invite students to guess as a way to assess and correct the student's knowledge. TEIREISIAS maps newly entered rules to rule models and proposes corrections based on how it expects a rule to follow the patterns of other rules in that model. EXPECT generates suggestions to a user about how to fix specific problems by making educated guesses about the context of the problem (related domain knowledge, past problem solving states, etc.)

Keep on track

Tutors need to keep track of the lesson and bring back issues that had to be dropped while engaging in clarifications or other side dialogues. Acquisition tools do not keep track of the history and status of the dialogue. Users have free range on what aspects of the knowledge base to extend, what parts of the tool to invoke, and what They can move freely from topic to topic and back and forth, or discontinue teaching about a topic at any point without notifying termination. Current acquisition tools would never even notice that the user is deviating from a topic in any of these situations.

Indicate lack of understanding

Students often volunteer an indication of their lack of understanding, but tutors also will point out the specific aspects introduced in a lesson that the student needs to understand. INSTRUCTO-SOAR detects missing aspects of a task description specified by a user and generates follow up questions. EXPECT and CHIMAERA detect undefined terms that will be used to guide future dialogue with the user to define them.

Detect and fix "buggy" knowledge

Many tutoring systems are aimed to diagnose and fix student's "buggy" knowledge, often by asking questions and checking the student's answers. TAQL analyzes the knowledge specified by the user and points out errors based on static analysis. CHIMAERA and EXPECT detect errors in the knowledge entered that need to be fixed by the user. PROTOS, SEEK2, and TEIREISIAS show explanations or traces to users so they can detect errors in the system's reasoning.

Learn deep models

Students should learn deep conceptual models instead of superficial ones. Knowledge acquisition tools do not have any basis to evaluate or pursue depth in their knowledge base, though this is a long

recognized shortcoming of knowledge-based systems. To date, these systems are at the mercy of the user's intention and of their implementation of any depth in the models.

Learn domain language

Students are expected to describe their knowledge in terms that are suitable for the domain at hand. Acquisition tools do not help users specify how to describe knowledge in domain terms and how the terminology used depends on the context of the scenario at hand. Knowledge bases are annotated with some lexical information, but acquiring this kind of knowledge has not been a focus of knowledge base development.

Keep track of correct answers

Instructional tools keep track of the questions that the student is able to answer correctly as well as those answered incorrectly, which drives further interactions with the student. SEEK2 keeps track of whether the test cases are answered correctly, and alerts the user when a change to a rule causes a case to be solved incorrectly.

Prioritize learning tasks

Tutoring systems often handle multiple sub-tasks using priority rules that look at the duration and type of task, for example focusing on fixing errors before turning to omissions. EXPECT organizes errors and other problems in the knowledge base based on their type and the amount of help it can provide (e.g., if it has narrowed down the options that the user can take to resolve them).

Limit the nesting of sub-lessons

Tutoring dialogue is sometimes controlled by limiting the amount of subdialogues, which helps the student keep track of the lesson topics.

Summarize what was learned

Many educational systems will summarize to the student the main highlights at the end of the lesson, especially if the student was given hints during the lesson. Acquisition tools do not summarize what they have learned.

Assess learned knowledge

Some instructional tools isolate weaknesses in the student's knowledge and propose further lessons on those areas, some students also volunteer their assessment of how well they understand certain topics. KSSn uses clustering techniques to suggest aspects of the model that users could detail further. Other acquisition tools do not perform this kind of analysis. Users often have to put the knowledge base through a performance system that exercises it in order to be able to assess if the knowledge was learned appropriately.

Discussion

Acquisition tools have used techniques that can be cast in terms of tutoring and learning principles found in educational software research. These principles are implicit in the design of the tool, and they influence their interaction with the user to the degree that they are implemented in the underlying code. Having these principles represented explicitly and declaratively would enable acquisition tools to reason in terms of the teaching and learning process, and their interaction with the user would be dynamically generated given the situation at hand. A declarative representation of meta-knowledge about their learning state, goals, and possible strategies could turn interactive acquisition tools into more proficient and proactive learners.

The principles have only been used in some aspects of the functionality of acquisition tools, and are exhibited by some but not all the tools. The sparseness of the matrix in Table 2 points to many opportunities for future work in incorporating these principles. By having declarative representations of their learning state, goals, and possible strategies, interactive acquisition tools could more easily incorporate these principles throughout the acquisition process and the five functions shown in the table.

Acquisition interfaces should be able to structure the dialogue with the user in tutoring terms. The should organize the dialogue based on lesson topics and sub-topics, be aware of the start and the end of each and generally keep the user on track and delaying termination until the goals of the lesson are satisfied. Acquisition tools should exploit the topics of the lesson throughout the acquisition process, for example to narrow down the prior knowledge that is relevant to that portion of the dialogue and consequently narrowing down the proposed strategies and customizing the presentation of information back to the user. By keeping track of the interactions with the user, the topic of the dialogue at each point in time, and the termination of sub-topics, acquisition tools would be able to manage their participation in the dialogue better and relieve the users from having to remember and keep track of what is going on. They could exploit this information in generating goals by detecting areas where a topic is still unfinished, plan and prioritize more relevant strategies that exploit the context of the currently open topics, and help users view progress and termination.

Acquisition tools should be able to expose and assess the knowledge acquired so far, allowing the user to understand what the system has assimilated and showing the user as well what areas the system thinks need to be further improved. Currently, knowledge-based systems will answer any question they are asked, regardless of the quality of the knowledge used to answer it. It would be very useful for these systems to convey whether they are confident on the answer. This would also help users identify

further areas of improvement for future acquisition sessions.

We are pursuing these ideas in our current work, implementing a front-end dialogue management system that represents and uses tutoring and learning principles to guide knowledge acquisition.

Abstract

We study how Extraversion or Introversion influences people's language production. A corpus of e-mail texts was gathered from individuals categorised via Eysenck's EPQ-R personality test. One experiment analysed the corpus using existing content analysis tools, and found relatively weak effects of Extraversion. A second experiment used more sensitive bigram-based techniques from statistical natural language processing to replicate earlier findings, and uncover novel patterns of behaviour.

Introduction

Casual acquaintance with Extraverts¹ and Introverts suggests that the former talk a lot more than the latter. But apart from this intuitive difference, how does this personality dimension influence an individual's language production? Before addressing this question, we need to clarify what we mean by Extraversion, and its relevance to cognitive science.

A typical Extravert tends to be sociable, needs people to talk to, craves excitement, takes chances, is easy-going, and optimistic. By contrast, a typical Introvert is quiet, retiring, reserved, plans ahead, and dislikes excitement (Eysenck and Eysenck, 1991).

The personality trait of Extraversion—and the complementary Introversion—is one of the few which researchers generally agree provides 'consistent and valid information' (Jonassen and Grabowski, 1993). Beyond it, there is greater controversy.

For instance, Eysenck's EPQ-R personality test reflects a personality model which incorporates just two further dimensions: Neuroticism, which is mainly characterised by susceptibility to anxiety; and Psychoticism, which is more complicated, but generally related to aggression and individuality. By contrast, the NEO-PI-R model incorporates five factors (Costa and McCrae, 1992). As well as Extraversion and Neuroticism, there are Conscientiousness, Agreeableness and Openness. It is generally agreed that these relate to Psychoticism, but exactly how is

¹The spelling of follows Eysenck, because this paper employs his EPQ-R as the measure of personality, but this does not represent a commitment to a specifically Eysenckian theory of personality.

still the subject of debate (cf. Matthews and Deary, 1998).

Extraversion, and its linguistic consequences—if there are any—is relevant to cognitive research for at least two reasons. First, there is considerable evidence that this personality dimension is related to preferred learning styles and educational achievement, via speed of exam completion, memory retrieval and recall tasks, creativity, mathematical ability, self monitoring and communication ability (Jonassen and Grabowski, 1993). Secondly, there is evidence that computer users attribute personality to interfaces, and respond to it in robust ways (eg. Nass, Moon, Fogg, and Reeves, 1995; Isbister and Nass, 2000). Even in a text-only environment, Extraverts apparently prefer interfaces presenting information using language associated with Extravert traits; Introverts prefer Introverted interfaces. An interface with a matching personality is judged more positively, and rated as more attractive, credible and informative (Nass *et al.*, 1995).

So the personality dimension has some validity, and appears relevant to the diagnosis and projection of personality in human-computer communication, and in computer-based learning. But how does Extraversion influence an individual's language production? In addressing this question, we first outline some hypotheses from the literature, before describing our collection of a controlled corpus of language, and our analysis of it. We then report the results—some unsurprising, others unexpected—and discuss some of their implications.

Previous hypotheses

Work on textual personality within the "Computers Are Social Actors" paradigm has taken the expressive hallmarks of Extraversion or *dominance* (one facet of the dimension) to be confidence, as shown by an avoidance of hedge-expressions such as *perhaps* and *maybe* (Nass *et al.*, 1995), and is related to the empirical work of Bradac and Mulac (1984) on perceptions of powerful and powerless speech.

From an intuitive perspective, Extraverts are described as individuals who think out loud, do most of the talking, are less self-focussed, and tend to skip from topic to topic. Conversely, Introverts mo-

nopolise the conversation on topics important to them, are more self-focussed and prefer to concentrate on discussing one topic in depth (cf. Carment, Miles, and Cervin, 1965). With reference primarily to speech, Furnham (1990) has proposed that Extravert language is less formal, has a more restricted code, uses more verbs, adverbs and pronouns (rather than nouns, adjectives, and prepositions), and uses vocabulary loosely (see also Dewaele and Furnham, 1999, for a review of speech and writing studies).

Text analysis approaches have found that transcribed texts rated as belonging to the *warm* facet of Extraversion used fewer negative emotion words and unique words, and more present tense verbs, with *dominant* texts using fewer unique words, positive emotion words and self referents (Berry, Pennebaker, Mueller, and Hiller, 1997). Finally, study of the texts *written* by Extraverts has found that they used fewer negations, tentative words, negative emotion words, causation words, inclusive words, and exclusive words, while using more social and positive emotion words (Pennebaker and King, 1999).

Data Collection

The approach to data collection follows Pennebaker and King (1999). Written texts were collected from 105 University students or recent graduates (37 males, 68 females; mean age = 24.3 years; SD = 4.6; all native English speakers). An introductory e-mail explained the experiment, and pointed subjects to the relevant web-page. After the completion of an online demographic questionnaire and a version of the Eysenck Personality Questionnaire (Revised short form; Eysenck, Eysenck, and Barrett, 1985) (mean score for E = 7.91, SD = 3.25; normative score = 7.42 (male), 7.60 (female)), subjects were asked to compose two e-mails to a *good friend whom they hadn't seen for quite some time*, the style of which is considered to be close to oral communication (Bälter, 1998). One message concerned their activities in the past week; the other discussed their plans for the next week. Subjects were advised to spend around ten minutes per message, composed online and submitted using an HTML form. It was highlighted that responses would be treated in confidence and that subjects could remain anonymous. No payment was made for participation, and integrity of responses was monitored by reading through the transcripts. One additional submission was rejected as not being serious; the resulting corpus contained 210 texts and 65,000 words.

Experiment 1: Dictionary techniques

LIWC and MRC Methods

LIWC Each respondent's texts were individually processed using the LIWC text analysis program (Pennebaker and Francis, 1999). Items were selected

Table 1: Summary of E Score and LIWC multiple regression analysis.

Dependent Variable	Independent Variable	β	R^2	p
E Score	Numbers	-.21	.08	.0144
	Word Count	.20		

for principle components analysis using the same criteria as Pennebaker and King (1999), namely reliability, topic independence, independence from other variables, and a mean minimum usage of 1%. The validity of the current data was shown using varimax rotation to derive four factors which essentially replicate their prior findings. There was minor variation in some factor loadings, which we attribute to differences in the writing tasks. See Gill and Oberlander (prep) for a fuller discussion.

By correlating their resultant LIWC factors with personality dimensions, Pennebaker and King's results suggest broad style preferences for Extraverts. But this does not identify the relative importance of their categories for identifying text as Extravert.

Thus, to identify which LIWC variables best help identify an author's personality, stepwise linear multiple regression was performed. The variables entered were those which showed at least a small correlation with the personality type—with a significance of $p < .1$ —and which satisfied the criteria for inclusion in the previous principle components analysis. However, since requiring variables to have a mean usage of 1% per essay for inclusion in the analysis did not leave any LIWC variables in the regression equation for Extraversion, this criterion was ignored for the results presented below. (Interestingly, by contrast, even with the application of this criterion, Psychoticism and Neuroticism both had several strongly significant LIWC predictor variables.)

MRC In addition to the LIWC-based tests, multiple regression analysis was also performed on psycholinguistic properties of the texts, derived from the MRC Psycholinguistic Database (Coltheart, 1981). Texts were first tagged for Parts of Speech,² and each word-POS pair was then looked up in the database. If the word and POS tag matched a pair in the database, psycholinguistic data was returned for that word. When all the words in the text had been processed, mean scores were calculated for categories such as verbal frequency, written frequency, concreteness, age of acquisition, along with additional global information, such as the percentage of a text's words which were captured by the database. As with the LIWC regression, variables showing a correlation with the personality type with a significance of $p < .1$ were entered in to the equation.

²Using the MXPOST tagger (Ratnaparkhi, 1996).

Table 2: Summary of E Score and MRC multiple regression analysis.

Dependent Variable	Independent Variable	β	R^2	p
E Score	Mean Concreteness	-.21	.05	.0278

Results

The multiple regression analysis of the LIWC variables (Table 1) shows that a greater overall word count for a text ($\beta = .20$), and the occurrence of fewer references to numbers within that text ($\beta = -.21$), indicate Extraversion ($p < .05$). So, Extraverts *do* appear to type more than Introverts, mirroring earlier results on speech (Carment *et al.*, 1965), with the avoidance of numbers embodying a 'looser', less precise use of language (Furnham, 1990). However, the variance accounted for by these variables is relatively low at 8%. In comparable analyses, both Psychoticism and Neuroticism regression equations explain variance greater than 10%.

Similarly, with the MRC Psycholinguistic analysis (Table 2), only the novel finding of a general lowering of a text's concreteness of vocabulary ($\beta = -.21$, $p < .05$) was seen to explain 5% of variance in Extraversion. Again, equations for Psychoticism and Neuroticism explained more than 10% of variance.

Discussion

In both of the dictionary-based analyses of the texts, rather few features appeared to distinguish Extravert/Introvert texts, especially when compared to the numerous LIWC and MRC features which associated with Psychoticism and Neuroticism traits.

How could this be? At least two explanations are possible. First, the LIWC dictionary is a subjectively constructed analysis tool. It is based on judgements by health psychologists of texts written by distressed individuals for therapeutic purposes (Pennebaker and Francis, 1999). For its original purposes, this is a strength; but it also imposes a *top down* limitation on LIWC's functioning. Given this therapeutic origin, it is tempting to suggest that the linguistic features associated with the personality traits of Psychoticism and Neuroticism were more important or relevant to the distressed individuals producing the texts—and that is why these features are better represented in LIWC's dictionary.

The MRC database is also fitted to its specific purposes—for example, matching psycholinguistic stimuli—but this again imposes constraints which might prove artificial when it is applied to a different area of investigation.

Secondly, both dictionaries necessarily operate using strings corresponding to individual words, subsequently classifying them in a predefined way. Neither takes into account the context of a word. Thus

it may be that for Psychoticism and Neuroticism the choice of word, or some property of the word is informative—but for Extraverts, it may be that word order or collocations are more relevant.

Experiment 2: NLP techniques

Therefore, we recruit *bottom up* statistical text analysis techniques from corpus linguistics. Specifically, bigram analysis calculates the probability of pairs of adjacent terms, or bigrams, occurring together in that order in a given text. To determine the significance of a bigram's occurrence, a statistic—log likelihood—is calculated, taking into account all the other instances of each element in the bigram pair, and the other words with which they appear.

Since bigrams can be used to calculate the probabilistic space in which language occurs, they have been put to a variety of uses (Collins, 1996; Pedersen, 2001). However, this study uses them simply as an advancement on the classified unigram (that is, single-word) analysis in Experiment 1. Because bigrams contain information about the interconnection and dependencies of words, this second analysis retains some of the contextual information of language use. Equally importantly, since bigrams are not classified subjectively, they provide a form of analysis that is bottom-up, rather than top-down.

Method

The original corpus of texts was divided by degree of Extraversion by selecting respondents whose E score was greater or less than 1 s.d. of the mean (cf. Dewaele and Pavlenko, 2002), with the 21 High Extravert authors scoring more than 11, and the 17 Low Extravert authors scoring less than 5.

Bigrams were calculated for the resulting Extravert and Introvert subcorpora; the former contained over 12,000 words; the latter around 8,000. Bigram profiles were generated for each corpus and their co-occurrence significance in the current texts ranked by log-likelihood statistic ($-2 \log \lambda$),³ since for smaller corpora this approximates better to χ^2 than the X^2 statistic (Dunning, 1993). Rankings for each group are based on the top 50 bigrams with frequency of $N \geq 2$, and a significance of $p < .001$. Relative frequency ratios (Damerau, 1993) were then calculated for bigrams that were common to both the subcorpora, and a Spearman Rank correlation was also performed on these bigrams.

Results

Spearman Rank Correlation

The correlation coefficient score of .53 indicates that Extravert and Introvert use of the shared bigrams is significantly correlated at the $p < .005$ (one-tailed, $N=28$) level, and they are therefore not distinct.

³Ted Pederson's bigram software is available from: <http://www.d.umn.edu/~tpedersen/code.html>.

However, further analysis showed Extraverts to be more distinguishable from Ambiverts or Introverts.⁴

Extraverts versus Introverts

The results of the bigram analysis include: bigrams which occurred in both the Extravert and Introvert corpora (Table 3); bigrams which were found uniquely in the Extravert corpus (Table 4); and those found only in the Introvert corpus (Table 5). The shared bigrams are ordered by their relative frequency, with the highest ratios above 1.0 showing the strongest association with Extravert authors, and the smallest ratios less than 1.0 indicating a preference on the part of more Introverted authors (the breakpoint has been indicated by a separating rule). Features which are unique to each subcorpus group can be considered the most distinctive of authorial personality. For current purposes, we divide the features into eight groupings.

Surface Realisation Features These gross features are perhaps the most intuitive in their representation of the Extraverts or Introverts. For example, [`<END> hi`], the `<END>` (end-of-file marker)

⁴When comparing the groups High E (≥ 1 s.d.), Mid E ($< \pm 1$ s.d.) and Low E (≤ -1 s.d.) (all P and N $< \pm 1$ s.d.) it was found that Low E and Mid E correlate very significantly ($p < .005$; $\rho = .67$; $N = 19$), whilst High E and Mid E do not significantly correlate at the $p < .05$ level ($\rho = .32$; $N = 24$).

Table 4: Bigrams unique to Extravert corpus.

take care	23	96.00	8	0.0006
catch up	39	70.50	7	0.0005
other than	49	62.84	6	0.0005

followed by *hi*, was unique to Extravert texts; and since the `<END>` marker separates concatenated files in the corpus, here we have a tendency towards message-initial *hi*. By contrast the more formal [`<END> hello`] was found solely in Introvert texts. Use of punctuation also differs between the two groups, with Extraverts preferring multiple exclamation marks [`! !`], and solely using multiple full stops [`. .`] as in the elliptical (`. . .`), again a feature of informal style, and 'looser' use of language.

Quantification In terms of quantification, Introverts generally tend to show a preference for a greater use of quantifiers, such as [*a lot*], [*a few*] and uniquely [*all the*], [*one of*], [*lots of*] and [*loads of*], whereas Extraverts show a preference for [*a bit*] and uniquely use [*couple of*]. Not only does this demonstrate an Extravert tendency to be looser and less specific, it also apparently reveals exaggeration on the part of the Introvert.

Social Devices The Extravert use of stylistic expressions such as [*catch up*] and [*take care*] indicate a relaxed and informal style; their omission points to a more socially restrained Introvert. A surprisingly neat equivalence in expression can be found between the Extravert use of [*other than*] rather than [*apart from*], although it is not immediately clear what might give rise to this.

Self/Other Reference References to self in the texts demonstrate differences between Extraverts and Introverts: Introverts make extensive use of the first person singular pronoun ([*i don't*], [*i went*], [*i'm going*], [*i can*], [*i've got*] are all unique to the Introvert text), and also show preference for the following shared bigrams: [*i've done*], [*i think*], [*i am*], [*. i*].

Table 5: Bigrams unique to Introvert corpus.

exam results	42	47.26	3	0.0003

For Extraverts, the only unique first person bigram is [*i'll be*], and they also show greater use of [*i was*] and [*i will*], although relatively less preferred than Introvert forms. This underscores the increased Introvert tendency to focus on self, whereas the only bigram containing a first person plural is unique to Extraverts ([*we went*]). The Extravert preference for the bigram [*up with*] typically indicates a shared experience (prompting the question *with whom?*) and greater sociability. These results apparently contradict Furnham (1990) on pronouns, but given that the vast majority of pronouns here are first-person singular, thus focusing on self, this is unsurprising.

Valence Bigrams containing negations were used significantly only by Introverts, as in [*i don't*] and [*don't know*] (indeed [*i don't*] is the bigram with most frequent use of *i*), whilst Extraverts used the bigram [*a good*] which is suggestive of positive affect.⁵ Similarly, the Extravert preference for [*looking forward*] and [*forward to*] (presumably as in *looking forward to*) also suggests a more positive disposition.

Ability Personal views on capability are suggested by the different collocations with infinitival *to*.⁶ For Extraverts, their ability to do something should they choose is confidently and assertively relayed using *want-*, *need-*, and *able-* (*to*); which they use uniquely. Introverts more timidly and tentatively

⁵Further investigation shows that is not directly negated (as in [.....]). Compare the Introvert [.....], which was generally followed by Although the effect of negation was not viewed as important by Pennebaker in the functioning of LIWC, it certainly has implications for models of language generation.

⁶This confirms the appropriacy of retaining functors usually filtered out by a stop list (cf. Damerau, 1993).

state that they are [*trying to*] or possibly—and at some point in the future—they are [*going to*].

Modality Similarly, collocations with the verb *be* show a distinction in use of modal auxiliaries which has an effect on the projection of certainty. For example, Introverts are unique in their use of the weaker and more tentative *should be*, whereas Extraverts show a greater use of the stronger predictive [*will be*], and are unique in their use of the contracted form [*i'll be*] (*i will be*) (Coates, 1983).

Message Planning/Expression Looking towards surrogates of grammatical construction, Extraverts and Introverts differ in their use of connectives: Introverts show preference for the coordinating conjunctions [*and*] and [*but*], whilst Extraverts uniquely show use of the subordinating [*which*], usually deployed in an evaluative sense.

Discussion

In summary, our results support earlier findings, and suggest some new conclusions.

We found that Extraverts produce texts with more words, which supports the previous findings for speech (Carment *et al.*, 1965), whilst the reduced concreteness of Extravert language is a novel finding. It may be a direct consequence of talking or writing more, if the pressure to produce words at a high rate (in order to hold the floor, for instance) diverts resources away from more detailed lexical planning. Introverts' greater preference for numbers and quantification fits with this, and is compatible with findings concerning the use of articles (Pennebaker and King, 1999), and suggestions of a more imprecise and 'looser' Extravert style (Furnham, 1990).

Extraverts' use of other or social referents, and Introverts' preference for self referents confirms Berry *et al.* (1997)'s previous findings for Extraversion and its *dominant/submissive* facets. Another possible manifestation of the increased Extravert social ability and ease in interaction is expressed by their use of surface features and social devices. We also note in passing the tendency of Extraverts to refer to days of the weekend, where Introverts refer to weekdays.

Our results on valence are consistent with previous findings on Introverts' preference for negations and negative emotion words, and the Extravert tendency for positive affect words is consistent with results for *warmth*. However, they do suggest that care should be taken over the relation between Extraversion and *dominant* facet features (cf. Isbister and Nass, 2000).

Expressions of definite modality and ability appear to be associated with Extraversion, although they may not be the same forms as those discussed in the context of powerful/less speech. Adoption of definite modalities can also be related to avoidance of tentativeness (Pennebaker and King, 1999).

Turning to connectives, we note that our Introvert

preference for [, and] and [, but] is consistent with studies using LIWC which found that the dictionary categories of Inclusion and Exclusion were both inversely correlate with Extraversion. However, [other than] and [apart from] would both fall into the same LIWC category, yet appear to distinguish opposite ends of the personality dimension.

Conclusion

By combining techniques from psycholinguistics and statistical natural language processing, we have been able to replicate previous findings on the expression of Extraversion through language, and uncover some new linguistic behaviours. Where existing content analysis tools could not detect reliable differences, more sensitive linguistic tools proved their worth.

Further, more technically sophisticated analyses can be carried out on this data, and we envisage the use of machine learning techniques to identify distinctive features from the texts, along with bigram analysis exploiting Parts of Speech tags. Additionally, the role of gender could be investigated.

Our findings could be exploited within the field of automatic language generation. As they stand, stochastic techniques would be needed; however, a cognitively-based personality model would allow a deeper approach, and that is our eventual goal.

Abstract

We explore one aspect of meaning, the identification of matching concepts across systems (e.g. people, theories, or cultures). We present a computational algorithm called ABSURDIST (Aligning Between Systems Using Relations Derived Inside Systems for Translation) that uses only within-system similarity relations to find between-system translations. While illustrating the sufficiency of within-system relations to account for translating between systems, simulations of ABSURDIST also indicate synergistic interactions between intrinsic, within-system information and extrinsic information.

Conceptual Meaning and Translation

There have been two major answers to the question of how our concepts have meaning. The first answer is that concepts' meanings depend on their connection to the external world (Harnad, 1990). By this account, the concept Dog means what it does because our perceptual apparatus can identify features that characterize, if not define, dogs. Dog is characterized by features that are either perceptually given, or can be reduced to features that are perceptually given. This will be called the "external grounding" account of conceptual meaning. The second answer is that concepts' meanings depend on their connections to each other (Markman & Stillwell, 2001; Saussure, 1915/1959). By this account, Dog's meaning depends on Cat, Domesticated, and Loyal, and in turn, these concepts depend on other concepts, including Dog. The dominating metaphor here is of a conceptual web in which concepts all mutually influence each other (Quine & Ullian, 1970). A concept can mean something within a network of other concepts but not by itself. This will be called the "conceptual web" account.

The goal of this article is to argue for the synergistic integration of conceptual web and externally grounded accounts of conceptual meaning. However, in pursuing this argument, we will first argue for the sufficiency of the conceptual web account for a particular task associated with conceptual meaning. Then, we will show how the conceptual web account can be ably supplemented by external grounding to establish meanings more successfully than either method could by itself.

Our point of departure for exploring conceptual meaning will be a highly idealized and purposefully simplified version of a conceptual translation task. Consider two individuals, Joan and John, who each possesses a

number of concepts. Suppose further that we would like some way to tell that Joan and John both have a concept of, say, **Mushroom**. Joan and John may not have exactly the same concept of **Mushroom**. John may believe mushrooms grow from seeds whereas Joan believes they grow from spores. More generally, Joan and John will differ in the rest of their conceptual networks because of their different experiences and levels of expertise. Still, it seems desirable to say that Joan and John's **Mushroom** concepts correspond to one another. We will describe a network that translates between concepts in two systems, placing, for example, Joan and John's **Mushroom** concepts in correspondence with each other.

Translation across systems is generally desirable and specifically necessary in order to say things like "John's concept of mushrooms is less informed than Joan's." Fodor and Lepore have taken the existence of this kind of translation as a challenge to conceptual web accounts of meaning (Fodor & Lepore, 1992). By Fodor and Lepore's interpretation, if a concept's meaning depends on its role within the larger system, and if there are some differences between the systems, then the concept's meaning would be different in the two systems. A natural way to try to salvage the conceptual web account is to argue that determining corresponding concepts across systems does not require the systems to be identical, but only similar. However, Fodor (Fodor, 1998; Fodor & Lepore, 1992) insists that the notion of similarity is not adequate to establish that Joan and John both possess a **Mushroom** concept. Fodor argues that "saying what it is for concepts to have similar, but not identical contents presupposes a prior notion of beliefs with similar but not identical concepts" [Fodor, 1998, p. 32].

The ABSURDIST Algorithm for Cross-system Translation

We will now present a simple neural network called ABSURDIST (Aligning Between Systems Using Relations Derived Inside Systems for Translation) that finds conceptual correspondences across two systems (two people, two time slices of one person, two scientific theories, two developmental age groups, two language communities, etc.) using only inter-conceptual similarities, not conceptual identities, as input. Thus, ABSURDIST will take as input two systems of concepts in which every concept of a system is defined exclusively in terms of its dissimilarities to other concepts in the same system. Laakso and

Cottrell (2000) describe another neural network model that uses similarity relations within two systems to compare the similarity of the systems. ABSURDIST produces as output a set of correspondences indicating which concepts from System A correspond to which concepts from System B. These correspondences serve as the basis for understanding how the systems can communicate with each other without the assumption made by Fodor (1998) that the two systems have exactly the same concepts. The existence of ABSURDIST provides evidence against Fodor's argument that similarities between people's concepts are an insufficient basis for determining that two people share an equivalent concept. ABSURDIST is not a complete model of conceptual meaning or translation. Our point is that even if the only relation between concepts in a system were simply similarity, this would still suffice to find translations of the concepts in different systems.

Elements $A_{1..m}$ belong to System A, while elements $B_{1..n}$ belong to System B. $C_i(A_q, B_x)$ is the activation, at time t , of the unit that represents the correspondence between the q th element of A and the x th element of B. There will be $m \cdot n$ correspondence units, one for each possible pair of corresponding elements between A and B. In the current example, every element represents one concept in a system. The activation of a correspondence unit is bound between 0 and 1, with a value of 1 indicating a strong correspondence between the associated elements, and a value of 0 indicating strong evidence that the elements do not correspond. Correspondence units dynamically evolve over time by the equations:

$$\text{if } N(C_i(A_q, B_x)) \geq 0 \text{ then } C_{i+1}(A_q, B_x) = C_i(A_q, B_x) + N(C_i(A_q, B_x))(\max - C_i(A_q, B_x))L \\ \text{else } C_{i+1}(A_q, B_x) = C_i(A_q, B_x) + N(C_i(A_q, B_x))(C_i(A_q, B_x) - \min)L \quad (1).$$

If $N(C_i(A_q, B_x))$, the net input to a unit that links the q th element of A and the x th element of B, is positive, then the unit's activation will increase as a function of the net input, a squashing function that limits activation to an upper bound of $\max=1$, and a learning rate L (set to 1). If the net input is negative, then activations are limited by a lower bound of $\min=0$. The net input is defined as

$$N(C_i(A_q, B_x)) = \alpha E(A_q, B_x) + \beta R(A_q, B_x) - \chi I(A_q, B_x), \quad (2)$$

where the E term is the external similarity between A_q and B_x , R is their internal similarity, I is the inhibition to placing A_q and B_x into correspondence that is supplied by other developing correspondence units, and $\alpha + \beta + \chi = 1$. When $\alpha=0$, then correspondences between A and B will be based solely on the similarities among the elements within a system, as proposed by a conceptual web account. The amount of excitation to a unit based on within-system relations is given by

$$R(A_q, B_x) = \frac{\sum_{r=1}^m \sum_{y=1}^n S(D(A_q, A_r), D(B_x, B_y)) C_i(A_r, B_y)}{\text{Min}(m, n) - 1},$$

where $D(A_q, A_r)$ is the psychological distance between elements q and r in System A, and S is a negative exponential function of the absolute difference between S 's two arguments. The amount of inhibition is given by

$$I(A_q, B_x) = \frac{\sum_{r=1}^m C_i(A_r, B_x) + \sum_{y=1}^n C_i(A_q, B_y)}{m + n - 2}.$$

According to the equation for R , Elements q and x will tend to be placed into correspondence to the extent that they enter into similar similarity relations with other elements. For influencing alignments, the similarity between two distances is weighted by the strengths of the units that align elements that are placed in correspondence by the distances. The equation for R represents the sum of the supporting evidence (the consistent correspondences), with each piece of support weighted by its relevance (given by the S term). The inhibitory I term is based on a one-to-one mapping constraint (Falkenhainer, Forbus, & Gentner, 1989). The unit that places A_q into correspondence with B_x will tend to become deactivated if other strongly activated units place A_q into correspondence with other elements from B, or B_x into correspondence with other elements from A.

Correspondence unit activations are initialized to random values selected from a normal distribution with a mean of 0.5 and a standard deviation of 0.05. In our simulations, Equation (1) is iterated for a fixed number of cycles. It is assumed that ABSURDIST places two elements into correspondences if the activation of their correspondence unit is greater than or equal to 0.55 after the fixed number of iterations have been completed (4000 cycles in the simulations described below).

Assessing ABSURDIST's Performance

In assessing ABSURDIST's performance, we will assume that conceptual dissimilarities obey Euclidean distance metric assumptions, and are interpretable as distances between concepts lying in a geometric space. Our general method for evaluating ABSURDIST will be to generate a number of elements in a two dimensional space, with each element identified by its value on each of the two dimensions. These will be the elements of System A, and each is represented as a point in space. System B's elements are created by copying the points from System A and adding Gaussian noise to each of the dimension values of each of the points. Then, equation (1) is used to update correspondences across the two systems for a fixed number of iterations. The correspondences computed by ABSURDIST are then compared to the correct correspondences. Two elements correctly correspond to each other if the element in System B was originally copied from the element in System A.

Noise tolerance and system complexity

An initial set of simulations was conducted to determine how robust the ABSURDIST algorithm was to noise and how well the algorithm scaled to different sized systems. We ran a 7×6 factorial combination of simulations, with 7 levels of added noise and 6 different numbers of elements per system. Noise was infused into the

algorithm by varying the displacement between corresponding points across systems. The points in System A were set by randomly selecting dimension values from a uniform random distribution with a range from 0 to 1000. System B points were copied from System A, and Gaussian noise with standard deviations of 0, 0.1, 0.2, 0.3, 0.4, 0.5, or 0.6% was added to the points of B. The number of points per system was 3, 4, 5, 6, 10, or 15. α was set to 0, β was set to 0.4, and χ to 0.6. The values for β and χ were selected because they were the most balanced weights that produced fewer than 5% two-to-one correspondences. For each of the 42 combinations of noise and number of items, 1000 separate randomized starting configurations were tested. The results from this simulation are shown in Figure 1, which plots the percentage of simulations in which each of the proper correspondences between systems is recovered. For example, for 15-item systems, the figure plots the percentage of time that all 15 correspondences are recovered. The graph shows that performance gradually deteriorates with added noise, but that the algorithm is robust to at least modest amounts of noise.

More surprisingly, Figure 1 also shows that the algorithm's ability to recover true correspondences generally increases as a function of the number of elements in each system, at least for small levels of noise. One might have thought that as more elements were matched between systems that there would be greater confusion between elements, given that the size of the bounding region re-

mains constant. As the number of elements in a system increases, the similarity relations between those elements provide increasingly strong constraints that serve to uniquely identify each element. If one generated random translations that were constrained to allow only one-to-one correspondences, then the probability of generating a completely correct translation would be $1/N!$. Thus, with 0.6% noise, the 23% rate of recovering all 3 correspondences for a 3-item system is slightly above chance performance of 16.67%. However, with the same amount of noise, the 17% rate of recovering all of the correspondences for a 15-item system is remarkably higher than the chance rate of 7.6×10^{-13} . Thus, at least in our highly simplified domain, we have support for the argument (Lenat & Feigenbaum, 1991) that establishing meanings on the basis of within-system relations becomes easier, not harder, as the size of the system increases.

Interactions between extrinsic and intrinsic determinants of alignments

The simulation above indicates that within-system relations are sufficient for discovering between-system translations, but this should not be interpreted as suggesting that the meaning of an element is not also dependent on relations extrinsic to the system. ABSURDIST offers a useful, idealized system for examining interactions between intrinsic (within-system) and extrinsic (external to

Figure 1

the system) aspects of meaning. One way to incorporate extrinsic biases into the system is by initially seeding correspondence units with values. Thus far, all correspondence units have been seeded with initial activation values tightly clustered around 0.5. However, in many situations, there may be external reason to think that two elements correspond to each other: they may receive the same label, they may have perceptual attributes in common, they may be associated with a common event, or a teacher signal may have provided a hint that the two elements correspond. In these cases, the initial seed-value may be significantly greater than 0.5.

Figure 2 shows the results of a simulation of ABSURDIST with different amounts of extrinsic support for a selected correspondence between two elements. Two systems are generated by randomly creating a set of points in two dimensions for System 1, and copying the points' coordinates to System 2 while introducing 0.6% noise to their positions. When Seed = 0.5, then no correspondence is given an extrinsically supplied bias. When Seed=0.75, then one of the true correspondences between the systems is given a larger initial activation than the other correspondences. For a system made up of 15 elements, a mapping accuracy of 31% is obtained without any extrinsic assistance (Seed=0.5). If seeding a single correct correspondence with a value of 1 rather than 0.5 allowed ABSURDIST to recover just that one correspondence with 100% probability, then accuracy would increase at most to 35.6% ($((.31 * 14) + 1)/15$). The reference line in Figure 2 shows these predicted increases in accuracy. For all systems tested, the observed increment in accuracy far outstretches the increase in accuracy predicted if seeding a correspondence only helped that correspondence. Moreover, the amount by which translation accuracy improves beyond the amount predicted generally increases as a function of system size. Thus, externally seeding a correspondence does more than just fix that correspondence. In a system where correspondences all mutually depend upon each other, seeding one correspon-

dence has a ripple-effect through which other correspondences are improved.

Equation 2 provides a second way of incorporating extrinsic influences on correspondences between systems. This equation defines the net input to a correspondence unit as an additive function of the extrinsic support for the correspondence, the intrinsic support, and the competition against it. Thus far, the extrinsic support has been set to 0. The extrinsic support term can be viewed as any perceptual, linguistic, or top-down information that suggests that two objects correspond (this differs from the philosopher's use of "external meaning" to refer to the causal determinants of a concept). To study interactions between extrinsic and intrinsic support for correspondences, we conducted 1000 simulations that started with 10 randomly placed points in a two-dimensional space for System A, and then copied these points over to System B with Gaussian-distributed noise. The intrinsic, role-based support is determined by the previously described equations. The extrinsic support term of Equation 2 is given by a negative exponential function of the absolute distance between the two concepts' absolute locations. Thus, the correspondence unit connecting q and x will tend to be strengthened if q and x have similar coordinates. This is extrinsic support because the similarity of q 's and x 's coordinates can be determined without any reference to other elements.

In conducting this third simulation, we assigned three different sets of weights to the extrinsic and intrinsic support terms. For the "Extrinsic only" results of Figure 3, we set $\alpha=0.4$, $\beta=0$, and $\chi=0.6$. For the "Intrinsic only" results, we set $\alpha=0$, $\beta=0.4$, and $\chi=0.6$. For "Intrinsic and Extrinsic," we set $\alpha=0.2$, $\beta=0.2$, and $\chi=0.6$.

Figure 3 shows that using only information intrinsic to a system results in better correspondences than using only extrinsic information. This is because corresponding elements that have considerably different positions in their systems can often still be properly connected with intrinsic information if other proper correspondences can be

Figure 2

recovered. The intrinsic support term is more robust than the extrinsic term because it depends on the entire system of emerging correspondences. For this reason, it is surprising that the best translation performance is found when intrinsic and extrinsic information are both incorporated into Equation 2 with equal weight. The superior performance of the network that uses both intrinsic and extrinsic information derives from its robustness in the face of noise. Some distortions to points of System B adversely affect the intrinsic system more than the extrinsic system. For example, a slight distortion to a point may make its pattern of distances to other points quite similar to another point. A system that incorporates both sources of information will tend to recover well from either disruption to absolute or relative positions if the other source of information is reasonably intact.

Discussion

The ABSURDIST model makes two theoretically important points. First, translations between two systems can be found using only information about the relations between elements within a system. The claim is that the concept in Person A that matches a concept in Person B can be found considering only the relations between concepts in Person A, and the relations between concepts in Person B. ABSURDIST demonstrates how a holistic conception of meaning is compatible with the goal of determining correspondences between concepts across individuals. Two people need not have exactly the same systems, or even the same number of concepts, to create proper conceptual correspondences. Contra Fodor (Fodor, 1998; Fodor & Lepore, 1992) information in the form of inter-conceptual similarities suffices to find inter-system

translations between concepts. It is often easier to find translations for large systems than small systems.

The second important theoretical contribution of ABSURDIST is to formalize some of the ways that intrinsic, within-system relations and extrinsic, perceptual information synergistically interact in determining conceptual alignments. Intrinsic relations suffice to determine cross-concept translations, but if extrinsic information is available, more robust, noise-resistant translations can be found. The synergistic benefit of combining intrinsic and extrinsic information sheds new light on the debate on accounts of conceptual meaning. It is common to think of intrinsic and extrinsic accounts of meaning as being mutually exclusive, or at least zero-sum. Seemingly, either a concept's meaning depends on information within its conceptual system or outside of its conceptual system, and to the extent that one dependency is strengthened, the other dependency is weakened. In opposition to this zero-sum perspective on intrinsic and extrinsic meaning, ABSURDIST offers a framework in which a concepts' meaning is both intrinsically and extrinsically determined (see also two-factor theories in philosophy such as Block, 1986), and the external grounding makes intrinsic information more, not less, powerful. To claim that all concepts in a system depend on all of the other concepts in a system is perfectly compatible with claiming that all of these concepts have a perceptual basis.

We have focused on the application of ABSURDIST to the problem of translating between different people's conceptual systems. However, the algorithm is applicable to a variety of situations in which elements from two systems must be placed in correspondence in an efficient and reasonable (though not necessarily optimal) manner. A

Figure 3

combination of properties makes ABSURDIST particularly useful for applications in cognitive science: 1) the algorithm can operate solely on relations within a system, 2) the within-system relations can be as simple as generic similarity relations, 3) the algorithm can combine within-system and between-systems information when each is available, 4) the algorithm has a strong bias to establish one-to-one correspondences, and 5) the algorithm does not require larger numbers of iterations for convergence as the number of elements per system increases. Some of the domains of application for ABSURDIST include object recognition, analogy, and automatic translation.

Object recognition

The ABSURDIST algorithm can be applied to the problem of object recognition that is invariant to translation, rotation, and reflection. For this application, a pictorial object is the system, and points on the object are elements of the system. A standard solution to recognizing rotated objects is to find matching landmark points that are identifiable on a known object and an input object to be recognized (Ullman, 1996). Once identified, these landmarks can reveal how the input would need to be rotated to match the known object. Even if no extrinsically aligned landmarks can be identified, ABSURDIST can still match the objects by taking advantage of the wealth of information contained in within-object proximity relations (Edelman, 1999).

Analogy

ABSURDIST offers a complementary approach to analogical reasoning between domains. Most existing models of analogical comparison represent the domains to be compared in terms of richly structured propositions (Hummel & Holyoak, 1997; Eliasmith & Thagard, 2001). In many cases, such as single words or pictures, it is difficult to come up with propositional encodings that capture an item's meaning. In such cases, ABSURDIST's unstructured similarity relations are a useful addition to existing models of analogical reasoning.

Automatic dictionary translation

The small-scale simulations conducted here leave open the promise of applying ABSURDIST to much larger translation tasks, such as dictionaries, thesauri, encyclopedias, and organizational structures. ABSURDIST could provide automatic translations between dictionaries of two different languages, using only co-occurrence relations between words within each dictionary (Burgess & Lund, 2000; Landauer & Dumais, 1997), perhaps supplemented by a small number of external hints (e.g. that French "chat" and English "cat" might correspond to each other because of their phonological similarity).

The Theory of Mind in Strategy Representations

Andrew S. Gordon (gordon@ict.usc.edu)

Institute for Creative Technologies, University of Southern California
13274 Fiji Way, Marina del Rey CA USA

Abstract

Many scientific fields continue to explore cognition related to Theory of Mind abilities, where people reason about the mental states of themselves and others. Experimental and theoretical approaches to this problem have largely avoided issues concerning the contents of representations employed in this class of reasoning. In this paper, we describe a new approach to the investigation of representations related to Theory of Mind abilities that is based on the analysis of commonsense strategies. We argue that because the mental representations of strategies must include concepts of mental states and processes, the large-scale analysis of strategies can be informative of the representational scope of Theory of Mind abilities. The results of an analysis of this sort are presented as a description of thirty representational areas that organize the breadth of Theory of Mind concepts. Implications for Theory Theories and Simulation Theories of Theory of Mind reasoning are discussed.

Investigating the Theory of Mind

One of the most challenging areas of research in the cognitive sciences has concerned the Theory of Mind, in reference to the abilities humans have to perceive and reason about their own mental states and the mental states of other people. Along with the inherent difficulties in investigating behavior that is largely unobservable, researchers in this area are required to be extremely interdisciplinary. Many research fields contribute evidence that influences our understanding of these human abilities, although the methods used to gather this evidence are diverse.

Researchers in developmental psychology largely choose to investigate the Theory of Mind as a set of abilities that progressively emerge in normal child development (Wellman & Lagattuta, 2000). By the last half of their second year, toddlers demonstrate an understanding of the role of intentionality in action, and that other people have subjective experiences. By the age of four and five, children comprehend and use vocabulary to refer to mental states such as thoughts, imaginations, and knowledge. As children advance into grade-school years and adulthood, there is a growing appreciation of people as active constructors and interpreters of knowledge, and awareness that others have ongoing thoughts. There is evidence that Theory of Mind capabilities continue to improve into the later

adult years, even while non-social reasoning abilities begin to degrade (Happé et al., 1998).

In the research area of abnormal psychology, compelling cases have been made relating illnesses such as autism (Baron-Cohen, 2000) and schizophrenia (Corcoran, 2001) to deficits in Theory of Mind abilities. Neuropathology studies of stroke patients have provided evidence that Theory of Mind mechanisms may be localized in the brain (Happé et al., 1999), and ongoing functional neuroimaging studies continue to provide further evidence for localization (Frith & Frith, 2000).

In search of a more process-oriented understanding of Theory of Mind abilities, it is the philosophy community that has made the most contributions, proposing two classes of process theories that have been extensively debated. First, the Theory Theory hypothesizes that Theory of Mind abilities are computed by prediction and explanation mechanisms by employing representation-level knowledge about mental attitudes (Gopnik & Meltzoff, 1997; Nichols & Stich, forthcoming). The opposing view is that of Simulation Theory (Goldman, 2000), which argues that Theory of Mind abilities are computed by imagining that you are in the place of the other person, then inferring their mental states by monitoring the processing that is done by your own cognitive mechanisms. While some high-level process-oriented cognitive models have been proposed (e.g. Nichols and Stich, 2000), there are many unanswered questions that prohibit the creation of detailed, computational models of Theory of Mind abilities.

Most lacking in our theoretical understanding of Theory of Mind abilities is a description of the specific *contents* of the mental representations that are employed in this reasoning. There is general agreement that these representational elements must include concepts such as *beliefs* and *desires* (e.g. Harris, 1996), and these two concepts in particular have taken a privileged role in the cognitive models that have been proposed. A potential benefit of the focus on these concepts is that this representational area (beliefs, desires, intentionality) is among the very few where established axiomatic theories have been developed in the artificial intelligence community (Cohen & Levesque, 1990). Continued artificial intelligence progress in developing axioms for inference concerning

mental states (e.g. Ortiz, 1998) will greatly support the plausibility of the Theory Theory approach.

However, there is a general sense throughout the fields investigating Theory of Mind abilities that the contents of these representations go far beyond simple notions of beliefs and desires, particularly among developmental psychologists investigating the role that language plays in acquiring mental state concepts. Several studies have been conducted that investigate the linguistic environment of children for the presence of Theory of Mind related terms, where the conceptual scope is much more broadly construed. Dyer et al. (2000) best exemplifies the broad conceptual scope of this line of work, which compared the frequency of 455 mental state terms that appear in young children's storybooks. This list included 102 cognitive state terms (e.g. notice, wonder), 152 emotional state terms (e.g. nervous, boring), 84 desire and volition terms (e.g. hope, wish), and 117 moral evaluation and obligation terms (e.g. ought, terrible), where the complete list was compiled from previous language studies.

While these linguistic approaches help to broaden our conception of the scope of representational elements in Theory of Mind reasoning, many of the traditional concerns about the relationship between language and mental representation may apply. Particularly, there is no reason to believe that any full enumeration of mental state terms must parallel the breadth of concepts that are represented and manipulated by reasoning processes. The inherent subjectivity of these concepts may serve to restrict the introduction of new vocabulary in the lexicon as compared with other topics of discourse. Likewise, the remarkable creativity that is evident in human language use may mislead us to believe that there are representational distinctions between concepts that are in fact functionally synonymous. While these linguistic approaches have been persuasive in arguing for a broader scope of Theory of Mind representations in our cognitive models, a new investigative methodology for concept enumeration would be useful.

Analogy as an Investigative Tool

In previous work (Gordon, 2001a), we argued that progress in a different area of cognition – that of analogical reasoning – could be a basis for a novel methodology for the investigation of mental representations. As a cognitive process, analogical reasoning has received an enormous amount of attention, both theoretical and experimental, with the aim of understanding how people draw analogies between two different cases in working memory. The prevailing explanation is based on the notion of structural alignment of the mental representations that people have of these cases (Gentner, 1983). That is, two different cases are judged as strongly analogous when

portions of the structured mental representation of one case can be mapped onto structurally identical portions of the other. Strong empirical support for the structure mapping theory of analogical reasoning (see Gentner & Markman, 1997, for a review) presents an opportunity: if structural alignment of representations are necessary to process analogies, then an analysis of the analogies that people naturally make can reveal the sorts of representations that they must employ.

In this previous work, two main claims were put forth. First it was noted that there is something particularly interesting about the commonsense notion of a strategy as it relates to analogies between planning cases. People readily see analogies between planning behaviors exhibited in vastly different goal-driven domains. For example, a retreating military force that destroys the supplies that they can't take with them may be viewed as analogous to the company that publicly releases its closely guarded industrial secrets in the face of a hostile corporate takeover. In both cases we would say the actors were using the same strategy, one that is so commonly recognized that it has been given a name, *scorched earth policy*. In accordance with the structure mapping theory of analogy, it was argued that strategies like this one are structured mental representations that are shared between the analogous planning cases where they are employed.

The second claim was that mental representations of strategies necessarily include references to the mental states and processes of people. For example, to be considered as an example of scorched earth policy, it must be the case that the actor foresees he will lose possession of a valuable resource to an advancing enemy, he foresees that after the enemy gains possession of it he will use the resource to further advance against him, and that the actor imagines that what he does to these resources will make them useless to the enemy. Strategic analogies show us that concepts such as these that specifically refer to mental processes must be explicitly represented in cognition. As the mental state concepts in these statements are exactly the sort relevant to Theory of Mind abilities, our claim is that the analysis of strategies provides a means of identifying the breadth of reified mental state concepts that are available in support of this class of reasoning.

In order to explore the representational scope of strategies, we undertook a large-scale strategy representation effort (Gordon, 2001b). First, 372 commonsense strategies were collected from 10 different planning domains using directed expert interviews, the analysis of texts that are encyclopedic of strategies in a particular domain, and the introspective elaboration of strategies in our own areas of expertise. To identify the representational requirements of this catalog of strategies, we developed a notational form called a *pre-formal representation* that would allow us

to commit to the specific semantic elements in the representation of a strategy without adhering to the syntactic constraints that would be necessary in more formal, logic-based representations. After authoring pre-formal representations of each of the 372 strategies, the component concepts were grouped into sets of synonyms to form a controlled vocabulary consisting of 989 unique concepts. This list was then organized into 48 representational areas that parallel both those that are traditionally the subject of formal commonsense knowledge representation (e.g. time and events) and those that are viewed as component cognitive processes in previous cognitive modeling work (planning and memory retrieval).

Eighteen of the representational areas that were identified in this previous work did not concern the mental states and processes of people. A large portion of these areas related more generally to the physical world, including concepts of time, space, events, states, objects, numbers, sets, and taxonomies. The remaining portion of these eighteen areas concerned people directly, but not their mental states in particular, and included terms for the relationships they hold, the organizations they participate in, their abilities, activities, and non-mental actions.

The other thirty representational areas that were identified deal specifically with the mental life of people. What is interesting about this collection of representational terms is that its scope is significantly larger than what has been suggested in cognitive models of Theory of Mind abilities or even in the contents of the lexicons used in the analysis of language for Theory of Mind concepts.

The primary direction in which these representational areas expand the scope of previous work is with respect to folk psychological conceptions of mental *processes*, whereas previous work has focused mostly on mental *states*. While the terms revealed in our investigation certainly include mental state concepts such as beliefs and desires, these are coupled with concepts describing the mental processes that affect these states, such as the mental processes of removing the justification for a belief and the process of abandoning of a goal to achieve some desired state. In short, the representations that appear to be necessary to account for strategic analogies outline a set of processes that constitute a cognitive architecture.

Theory of Mind Representations

In order to elaborate on the mental state and mental process components that are evident in the organization of strategy representation terms, this section briefly describes each of the thirty representational areas (of the 48 total) specifically related to Theory of Mind reasoning. Each area is listed with a short area title, the

number of unique representational terms (out of 989) in the area found in strategy representations, a short definition of the scope of the area, and a few examples of the specific terms in the area.

1. Managing knowledge (30 terms): The knowledge that agents have is a set of beliefs that may be true or false based on certain justifications, and can be actively assumed true, affirmed, or disregarded entirely. Examples: *Assumption, Justification, Revealed false belief*.

2. Similarity comparison (16 terms): Agents can reason about the similarity of different things using different similarity metrics, where analogies are similar only at an abstract level. Examples: *Class similarity, Similarity metric, Make analogy*.

3. Memory retrieval (3 terms): Agents have a memory that they use to store information through a process of memorization, and may use memory aids and cues to facilitate retrieval. Examples: *Memory cue, Memory retrieval, Memorize*.

4. Emotions (8 terms): Agents may experience a wide range of emotional responses based on their appraisal of situations, which defines their emotional state. Examples: *Anxiety emotion, Pride emotion, Emotional state*.

5. Explanations (17 terms): Agents generate candidate explanations for causes in the world that are unknown, and may have preferences for certain classes of explanations. Examples: *Candidate explanation, Explanation preference, Explanation failure*.

6. World envisionment (48 terms): Agents have the capacity to imagine states other than the current state, to predict what will happen next or what has happened in the past, and to determine the feasibility of certain state transitions. Examples: *Causal chain, Envisioned likelihood, Possible envisioned state*.

7. Execution envisionment (23 terms): One mode of envisionment is that of imagining the execution of a plan for the purpose of predicting possible conflicts, execution failures, side effects, and the likelihood of successful execution. Examples: *Envisioned failure, Side effect, Imagine possible execution*.

8. Causes of failure (31 terms): In attempting to explain failures of plans and reasoning, agents may employ a number of explanation patterns, such as explaining a scheduling failure by the lack of time, or a planning failure by a lack of resources. Examples: *False triggered monitor, Lack of ability, Successful execution of opposing competitive plan*.

9. Managing expectations (8 terms): Envisionments about what will happen next constitute expectations, which can be validated or violated based on what actually occurs. Examples: *Expectation violation, Unexpected event, Remove expectation*.

10. Other agent reasoning (8 terms): Envisionments about the planning and reasoning processes of other

agents allow an agent to imagine what they would be thinking about if they were them. Examples: *Guess expectation, Guess goal, Deduce other agent plan*.

11. Threat detection (15 terms): By monitoring their own envisionments for states that violate goals, an agent can detect threats and track their realization. Examples: *Envisioned threat, Realized threat, Threat condition*.

12. Goals (27 terms): Goals of agents describe world states and events that are desired, and include both states and events that are external to the planner as well as those that characterize desired internal mental states and processes. Examples: *Auxiliary goal, Knowledge goal, Shared goal*.

13. Goal themes (6 terms): A potential reason that an agent may have a goal could be based on the roles that agents have in relationships and organizations, or because of a value that they hold. Examples: *Generous theme, Good person theme, Retaliation theme*.

14. Goal management (28 terms): Agents actively manage the goals that they have, deciding when to add new goals, commence or suspend the pursuit of goals, modify or specify their goals in some way, or abandon them altogether. Examples: *Currently pursued goal, Goal prioritization, Suspend goal*.

15. Plans (32 terms): The plans of agents are descriptions of behaviors that are imagined to achieve goals, and can be distinguished by the types of goals that they achieve or by how they are executed, and may be composed of other plans or only partially specified. Examples: *Adversarial plan, Repetitive plan, Shared plan*.

16. Plan elements (28 terms): Plans are composed of subplans, including branches that are contingent on factors only known at the time of execution. They may have iterative or repetitive components, or include components that are absolutely required for a plan to succeed. Examples: *If then, Iteration termination condition, Triggered start time*.

17. Planning modalities (17 terms): The selection of plans can be done in a variety of different ways, such as adapting old plans to current situations, collaboratively planning with other agents, and counterplanning against the envisioned plans of adversaries. Examples: *Adversarial planning, Auxiliary goal pursuit, Imagined world planning*.

18. Planning goals (27 terms): The planning process is directed by abstract planning goals of an agent, which include goals of blocking threats, delaying events, enabling an action, preserving a precondition, or satisfying the goals of others. Examples: *Avoid action, Delay duration end, Maximize value*.

19. Plan construction (30 terms): Agents construct new plans by specializing partial plans, adding and ordering subplans, and resolving planning problems

when they arise. Examples: *Candidate plan, Planning failure, Planning preference*.

20. Plan adaptation (18 terms): Existing plans can be adapted and modified by substituting values or agency, and by adding or removing subplans to achieve goals given the current situation. Examples: *Adaptation cost, Adaptation failure, Substitution adaptation*.

21. Design (8 terms): One modality of planning is design, where the constructed plan is a description of a thing in the world within certain design constraints, and where the resulting things have a degree of adherence to this design. Examples: *Design adherence, Design failure, Designed use*.

22. Decisions (38 terms): Agents are faced with choices that may have an effect on their goals, and must decide among options based on some selection criteria or by evaluating the envisioned consequences. Examples: *Best candidate, Decision justification, Preference*.

23. Scheduling (23 terms): As agents select plans, they must be scheduled so that they are performed before deadlines and abide by other scheduling constraints. Plans may have scheduled start times and durations, or may be pending as the planner waits for the next opportunity for execution. Examples: *Deadline, Pending plan, Scheduling constraint*.

24. Monitoring (18 terms): Agents monitor both states and events in the world and in their own reasoning processes for certain trigger conditions which may prompt the execution of a triggered action. Examples: *First monitor triggering, Monitoring duration, Monitor envisionment*.

25. Execution modalities (11 terms): Plans can be executed in a variety of ways, including consecutively along with other plans, in a repetitive manner, and collaboratively along with other agents. Examples: *Concurrent execution, Continuous execution, Periodic execution*.

26. Execution control (28 terms): A planner actively decides to begin the execution of a plan, and may then decide to suspend or terminate its execution. A suspended plan can later be resumed from the point the agent left off. Examples: *Execution delay, Suspend execution, Terminate activity*.

27. Repetitive execution (16 terms): Some plans and subplans are executed iteratively for some number of times, or repetitively until some termination condition is achieved. Examples: *Current iteration, Iteration completion, Remaining repetition*.

28. Plan following (29 terms): Agents track the progress of their plans as they execute them in order to recognize when deadlines are missed, preconditions are satisfied, and when they have successfully achieved the goal. Examples: *Achieve precondition, Miss deadline, Successful execution*.

29. Observation of execution (29 terms): Agents can track the execution of plans by other agents, evaluating the degree to which these executions adhere to performance descriptions known to the observing agent. Examples: *Observed execution*, *Assessment criteria*, *Performance encoding*.

30. Body interaction (15 terms): The physical body of an agent translates intended actions into physical movements, and sometimes behaves in unintended ways. The body modifies the planner's knowledge through perception of the world around it, and by causing a sensation of execution. Examples: *Impaired agency*, *Nonconscious execution*, *Attend*.

Discussion

There exists no infallible technique for identifying the contents of the mental representations used in reasoning. The approach described here, where our theoretical understanding of analogical reasoning is used as an investigative tool, relies heavily on our analytic abilities in describing the shared relational structure of analogous cases as much as on the validity of the structure-mapping theory itself. We feel that while the specific concepts chosen in the course of authoring pre-formal representations of 372 strategies can rightly be questioned, the scope of these concepts as a whole cannot. The evidence provided by terms used in strategy representations suggests that the scope of mental representations that may support Theory of Mind abilities includes concepts for both the mental states of people and of the cognitive processes that they employ.

This evidence of process-oriented mental representations does not by itself provide support for either of the two prominent Theory of Mind theories (Theory Theory and Simulation Theory). However, it does have relevance to how proponents of these theories proceed to produce more detailed, even computational, process models of Theory of Mind abilities.

Proponents of the Theory Theory should view these representation areas as a catalog of the component theories that will be necessary to specify a complete folk psychology, in much the same way that artificial intelligence researchers have attempted to define the component theories of naïve physics (Hayes, 1985). If the two endeavors are indeed similar, then terms like those that comprise the representational areas listed here will appear as notations (predicates or otherwise) in formal axiomatic theories that could drive deductive reasoning. Because breadth of component theories for a full folk psychology appears to be at least as rich as those in naïve physics, we would expect that the same methodological problems in specifying these theories would prohibit progress (see Davis, 1998). As folk

psychology has received little attention within the artificial intelligence community as compared with naïve physics, few axiomatic theories exist today for the majority of the representational areas that are listed in this paper.

While axiomatic theories have not been forthcoming, most of these representational areas have been extensively studied as cognitive processes. Cognitive science and artificial intelligence researchers have constructed an enormous number of computational models in support of our theoretical understandings, with one notable exception of Theory of Mind reasoning itself (representational area 10, Other Agent Reasoning). For proponents of the Simulation Theory it is this set of computational models that will have to be employed in the off-line reasoning that allows a person to perform Theory of Mind tasks. Evidence of mental representations that correspond to these processes could suggest that there is a representational interface to support off-line reasoning. That is, terms like those in each of the representational areas could be viewed as a vocabulary for expressing inputs (e.g. commands and arguments) to these processes as well as their outputs (e.g. inferences). Further agreement within the cognitive modeling community concerning inputs and outputs could potentially promote the development of more modular computational theories, facilitating the integration of models that will be necessary in providing a process account of Simulation Theory, among others.

While the investigation of Theory of Mind representations may affect the theoretical debate only in the long run, its utility in linguistic studies of Theory of Mind language use may be more direct. Specifically, the identification of these representation areas – as well as the specific terms that appear in each – may be valuable in identifying a broader lexicon for use in the analysis of language data. For example, a process-oriented term such as *suspend goal* (from area 14, Goal Management) is expressible in a wide variety of ways in English, as in “Let's *put it off for now*” or “I'll *come back to it later*” where the direct object in both statements is the suspended goal. Compiling word and phrase lexicons for each of the terms in these representational areas could provide enough coverage over a language to facilitate more automated text analysis approaches, which in turn could greatly scale up the amount of linguistic data that could be analyzed.

Conclusions

While there has been great interest in understanding the Theory of Mind abilities of people, the experimental and theoretical approaches to this problem have largely avoided issues concerning the *contents* of representations employed in this class of reasoning. In

this paper, we have argued that progress in our understanding of a different cognitive process – that of analogical reasoning – provides us with a tool that can be used to investigate these representations in a new way. The curious nature of commonsense strategies, in accounting for analogies in planning domains and including references to mental states and processes, makes them a particularly important subject of analysis. By conducting a large-scale analysis of strategies from many planning domains, authoring pre-formal representations for each, we have improved the understanding of the scope of representations that would be available in support of Theory of Mind reasoning abilities. In addition to the mental state concepts that have traditionally been discussed in Theory of Mind research, this investigation suggests that rich representations of mental processes are also part of our representations.

A probabilistic approach to semantic representation

Thomas L. Griffiths & Mark Steyvers

Stanford, CA 94305-2130 USA

Abstract

Semantic networks produced from human data have statistical properties that cannot be easily captured by spatial representations. We explore a probabilistic approach to semantic representation that explicitly models the probability with which words occur in different contexts, and hence captures the probabilistic relationships between words. We show that this representation has statistical properties consistent with the large-scale structure of semantic networks constructed by humans, and trace the origins of these properties.

Contemporary accounts of semantic representation suggest that we should consider words to be either points in a high-dimensional space (eg. Landauer & Dumais, 1997), or interconnected nodes in a semantic network (eg. Collins & Loftus, 1975). Both of these ways of representing semantic information provide important insights, but also have shortcomings. Spatial approaches illustrate the importance of dimensionality reduction and employ simple algorithms, but are limited by Euclidean geometry. Semantic networks are less constrained, but their graphical structure lacks a clear interpretation.

In this paper, we view the function of associative semantic memory to be efficient prediction of the concepts likely to occur in a given context. We take a probabilistic approach to this problem, modeling documents as expressing information related to a small number of topics (cf. Blei, Ng, & Jordan, 2002). The topics of a language can then be learned from the words that occur in different documents. We illustrate that the large-scale structure of this representation has statistical properties that correspond well with those of semantic networks produced by humans, and trace this to the fidelity with which it reproduces the natural statistics of language.

Approaches to semantic representation

Spatial approaches Latent Semantic Analysis (LSA; Landauer & Dumais, 1997) is a procedure for finding a high-dimensional spatial representation for words. LSA uses singular value decomposition to factorize a word-document co-occurrence matrix. An approximation to the original matrix can be obtained by choosing to use less singular values than

its rank. One component of this approximation is a matrix that gives each word a location in a high dimensional space. Distances in this space are predictive in many tasks that require the use of semantic information. Performance is best for approximations that used less singular values than the rank of the matrix, illustrating that reducing the dimensionality of the representation can reduce the effects of statistical noise and increase efficiency.

While the methods behind LSA were novel in scale and subject, the suggestion that similarity relates to distance in psychological space has a long history (Shepard, 1957). Critics have argued that human similarity judgments do not satisfy the properties of Euclidean distances, such as symmetry or the triangle inequality. Tversky and Hutchinson (1986) pointed out that Euclidean geometry places strong constraints on the number of points to which a particular point can be the nearest neighbor, and that many sets of stimuli violate these constraints. The number of nearest neighbors in similarity judgments has an analogue in semantic representation. Nelson, McEvoy and Schreiber (1999) had people perform a word association task in which they named an associated word in response to a set of target words. Steyvers and Tenenbaum (submitted) noted that the number of unique words produced for each target follows a power law distribution: if k is the number of words, $P(k) \propto k^{-\gamma}$. For reasons similar to those of Tversky and Hutchinson, it is difficult to produce a power law distribution by thresholding cosine or distance in Euclidean space. This is shown in Figure 1. Power law distributions appear linear in log-log coordinates. LSA produces curved log-log plots, more consistent with an exponential distribution.

Semantic networks Semantic networks were proposed by Collins and Quillian (1969) as a means of storing semantic knowledge. The original networks were inheritance hierarchies, but Collins and Loftus (1975) generalized the notion to cover arbitrary graphical structures. The interpretation of this graphical structure is vague, being based on connecting nodes that "activate" one another. Steyvers and Tenenbaum (submitted) constructed a semantic network from the word association norms of Nelson et

Figure 1: The left panel shows the distribution of the number of associates named for each target in a word association task. The right shows the distribution of the number of words above a cosine threshold for each target in LSA spaces of dimension d , where the threshold was chosen to match the empirical mean.

al. (1999), connecting words that were produced as responses to one another. In such a semantic network, the number of associates of a word becomes the number of edges of a node, termed its “degree”. Steyvers and Tenenbaum found that the resulting graph had the statistical properties of “small world” graphs, of which a power law degree distribution is a feature (Barabasi & Albert, 1999).

The fact that semantic networks can display these properties reflects their flexibility, but there is no indication that the same properties would emerge if such a representation were learned rather than constructed by hand. In the remainder of the paper, we present a probabilistic method for learning a representation from word-document co-occurrences that reproduces some of the large-scale statistical properties of semantic networks constructed by humans.

A probabilistic approach

Anderson’s (1990) rational analysis of memory and categorization takes prediction as the goal of the learner. Analogously, we can view the function of associative semantic memory to be the prediction of which words are likely to arise in a given context, ensuring that relevant semantic information is available when needed. Simply tracking how often words occur in different contexts is insufficient for this task, as it gives no grounds for generalization. If we assume that the words that occur in different contexts are drawn from T topics, and each topic can be characterized by a probability distribution over words, then we can model the distribution over words in any one context as a mixture of those topics

$$P(w_i) = \sum_{j=1}^T P(w_i|z_i = j)P(z_i = j)$$

where z_i is a latent variable indicating the topic from which the i th word was drawn and $P(w_i|z_i = j)$ is the probability of the i th word under the j th topic. The words likely to be used in a new context can be determined by estimating the distribution over topics for that context, corresponding to $P(z_i)$.

Intuitively, $P(w|z = j)$ indicates which words are important to a topic, while $P(z)$ is the prevalence of those topics within a document. For example, imagine a world where the only topics of conversation are love and research. In such a world we could capture the probability distribution over words with two topics, one relating to love and the other to research. The difference between the topics would be reflected in $P(w|z = j)$: the love topic would give high probability to words like joy, pleasure, or heart, while the research topic would give high probability to words like science, mathematics, or experiment. Whether a particular conversation concerns love, research, or the love of research would depend upon the distribution over topics, $P(z)$, for that particular context.

Formally, our data consist of words $w = \{w_1, \dots, w_n\}$, where each w_i belongs to some document d_i , as in a word-document co-occurrence matrix. For each document we have a multinomial distribution over the T topics, with parameters $\theta^{(d_i)}$, so for a word in document d_i , $P(z_i = j) = \theta_j^{(d_i)}$. The j th topic is represented by a multinomial distribution over the W words in the vocabulary, with parameters $\phi^{(j)}$, so $P(w_i|z_i = j) = \phi_{w_i}^{(j)}$. To make predictions about new documents, we need to assume a prior distribution on the parameters $\theta^{(d_i)}$. The Dirichlet distribution is conjugate to the multinomial, so we take a Dirichlet prior on $\theta^{(d_i)}$.

This probability model is a generative model: it gives a procedure by which documents can be generated. First we pick a distribution over topics from the prior on θ , which determines $P(z_i)$ for words in that document. Each time we want to add a word to the document, we pick a topic according to this distribution, and then pick a word from that topic according to $P(w_i|z_i = j)$, which is determined by $\phi^{(j)}$. This generative model was introduced by Blei et al. (2002), improving upon Hofmann’s (1999) probabilistic Latent Semantic Indexing (pLSI). Using few topics to represent the probability distributions over words in many documents is a form of dimensionality reduction, and has an elegant geometric interpretation (see Hofmann, 1999).

This approach models the frequencies in a word-document co-occurrence matrix as arising from a simple statistical process, and explores the parameters of this process. The result is not an explicit representation of words, but a representation that captures the probabilistic relationships among words. This representation is exactly what is required for predicting when words are likely to be used. Because we treat the entries in a word-document co-occurrence matrix as frequencies, the representation developed from this information is sensitive to the natural statistics of language. Using a generative model, in which we articulate the assumptions about how the data were generated, ensures that we are

able to form predictions about which words might be seen in a new document.

Blei et al. (2002) gave an algorithm for finding estimates of $\phi^{(j)}$ and the hyperparameters of the prior on $\theta^{(d_i)}$ that correspond to local maxima of the likelihood, terming this procedure Latent Dirichlet Allocation (LDA). Here, we use a symmetric Dirichlet(α) prior on $\theta^{(d_i)}$ for all documents, a symmetric Dirichlet(β) prior on $\phi^{(j)}$ for all topics, and Markov chain Monte Carlo for inference. An advantage of this approach is that we do not need to explicitly represent the model parameters: we can integrate out θ and ϕ , defining model simply in terms of the assignments of words to topics indicated by the z_i .¹

Markov chain Monte Carlo is a procedure for obtaining samples from complicated probability distributions, allowing a Markov chain to converge to the target distribution and then drawing samples from the Markov chain (see Gilks, Richardson & Spiegelhalter, 1996). Each state of the chain is an assignment of values to the variables being sampled, and transitions between states follow a simple rule. We use Gibbs sampling, where the next state is reached by sequentially sampling all variables from their distribution when conditioned on the current values of all other variables and the data. We will sample only the assignments of words to topics, z_i . The conditional posterior distribution for z_i is given by

$$P(z_i = j | z_{-i}, w) \propto \frac{n_{-i,j}^{(w_i)} + \beta}{n_{-i,j}^{(\cdot)} + W\beta} \frac{n_{-i,j}^{(d_i)} + \alpha}{n_{-i,j}^{(d_i)} + T\alpha} \quad (1)$$

where z_{-i} is the assignment of all z_k such that $k \neq i$, and $n_{-i,j}^{(w_i)}$ is the number of words assigned to topic j that are the same as w_i , $n_{-i,j}^{(\cdot)}$ is the total number of words assigned to topic j , $n_{-i,j}^{(d_i)}$ is the number of words from document d_i assigned to topic j , and $n_{-i,j}^{(d_i)}$ is the total number of words in document d_i , all not counting the assignment of the current word w_i . α, β are free parameters that determine how heavily these empirical distributions are smoothed.

The Monte Carlo algorithm is then straightforward. The z_i are initialized to values between 1 and T , determining the initial state of the Markov chain. The chain is then run for a number of iterations, each time finding a new state by sampling each z_i from the distribution specified by Equation 1. After enough iterations for the chain to approach the target distribution, the current values of the z_i are recorded. Subsequent samples are taken after an appropriate lag, to ensure that their autocorrelation is low. Gibbs sampling is used in each of the following simulations in order to explore the consequences of this probabilistic approach.

¹A detailed derivation of the conditional probabilities used here is given in a technical report available at <http://www-psych.stanford.edu/~gruffydd/cogsci02/lda.ps>

Simulation 1:

Learning topics with Gibbs sampling

The aim of this simulation was to establish the statistical properties of the sampling procedure and to qualitatively assess its results, as well as to demonstrate that complexities of language like polysemy and behavioral asymmetries are naturally captured by our approach. We took a subset of the TASA corpus (Landauer, Foltz, & Laham, 1998), using the 4544 words that occurred both in the word association norm data and at least 10 times in the complete corpus, together with a random set of 5000 documents. The total number of words occurring in this subset of the corpus, and hence the number of z_i to be sampled, was $n = 395853$. We set the parameters of the model so that 150 topics would be found ($T = 150$), with $\alpha = 0.1$, $\beta = 0.01$.

The initial state of the Markov chain was established with an online learning procedure. Initially, none of the w_i were assigned to topics. The z_i were then sequentially drawn according to Equation 1 where each of the frequencies involved, as well as W , reflected only the words that had already been assigned to topics.² This initialization procedure was used because it was hoped that it would start the chain at a point close to the true posterior distribution, speeding convergence.

Ten runs of the Markov chain were conducted, each lasting for 2000 iterations. On each iteration we computed the average number of topics to which a word was assigned, $\langle k \rangle$, which was used to evaluate the sampling procedure for large scale properties of the representation. Specifically, we were concerned about convergence and the autocorrelation between samples. The rate of convergence was assessed using the Gelman-Rubin statistic \hat{R} , which remained below 1.2 after 25 iterations. The autocorrelation was less than 0.1 after a lag of 50 iterations.

A single sample was drawn from the first run of the Markov chain after 2000 iterations. A subset of the 150 topics found by the model are displayed in Table 1, with words in each column corresponding to one topic, and ordered by the frequency with which they were assigned to that topic. The topics displayed are not necessarily the most interpretable found by the model, having been selected only to highlight the way in which polysemy is naturally dealt with by this representation. More than 90 of the 150 topics appeared to have coherent interpretations.³

The word association data of Nelson et al. (1999) contain a number of asymmetries – cases where people were more likely to produce one word in response to the other. Such asymmetries are hard to ac-

²Random numbers used in all simulations were generated with the Mersenne Twister, which has an extremely deep period (Matsumoto & Nishimura, 1998).

Table 1: Nine topics from the single sample in Simulation 1. Each column shows 20 words from one topic, ordered by the number of times that word was assigned to the topic. Adjacent columns share at least one word. Shared words are shown in boldface, providing some clear examples of polysemy

count for in spatial representations because distance is symmetric. The generative structure of our model allows us to calculate $P(w_2|w_1)$, the probability that the next word seen in a novel context will be w_2 , given that the first word was w_1 . Since this is a conditional probability, it is inherently asymmetric. The asymmetries in $P(w_2|w_1)$ predict 77.47% of the asymmetries in the word association norms of Nelson et al. (1999), restricted to the 4544 words used in the simulation. These results are driven by word frequency: $P(w_2)$ should be close to $P(w_2|w_1)$, and 77.32% of the asymmetries could be predicted by the frequency of words in this subset of the TASA corpus. The slight improvement in performance came from cases where word frequencies were very similar or polysemy made overall frequency a poor indicator of the frequency of a particular sense of a word.

Bipartite semantic networks

The standard conception of a semantic network is a graph with edges between word nodes. Such a graph is unipartite: there is only one type of node, and those nodes can be interconnected freely. In contrast, bipartite graphs consist of nodes of two types, and only nodes of different types can be connected. We can form a bipartite semantic network by introducing a second class of nodes that mediate the connections between words. One example of such a network is a thesaurus: words are organized topically, and a bipartite graph can be formed by connecting words to the topics in which they occur, as illustrated in the left panel of Figure 2.

Steyvers and Tenenbaum (submitted) discovered that bipartite semantic networks constructed by humans, such as that corresponding to Roget's (1911) Thesaurus, share the statistical properties of unipartite semantic networks. In particular, the number of topics in which a word occurs, or the degree of that word in the graph, follows a power law distribution as shown in the right panel of Figure 2. This result is reminiscent of Zipf's (1965) "law of meaning": the

number of meanings of a word follows a power law distribution. Zipf's law was established by analyzing dictionary entries, but appears to describe the same property of language.

Figure 2: The left panel shows a bipartite semantic network. The right shows the degree distribution a network constructed from Roget's Thesaurus.

Our probabilistic approach specifies a probability distribution over the allocation of words to topics. If we form a bipartite graph by connecting words to the topics in which they occur, we obtain a probability distribution over such graphs. The existence of an edge between a word and a topic indicates that the word has some significant probability of occurring in that topic. In the following simulations, we explore whether the distribution over bipartite graphs resulting from our approach is consistent with the statistical properties of Roget's Thesaurus and Zipf's law of meaning. In particular, we examine whether we obtain structures that have a power law degree distribution.

Simulation 2:

Power law degree distributions

We used Gibbs sampling to obtain samples from the posterior distribution of the z_i for two word-document co-occurrence matrices: the matrix with the 4544 words from the word association norms used in Simulation 1, and a second matrix using

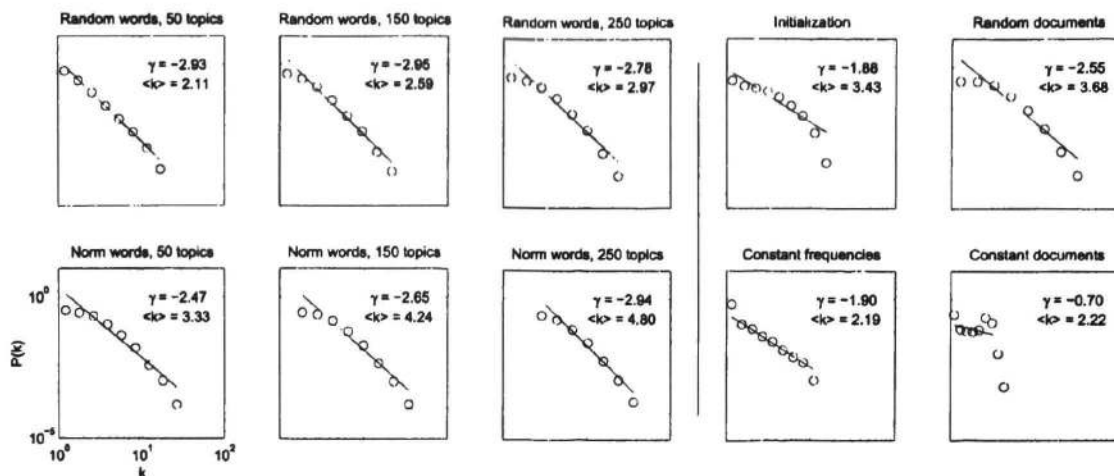

Figure 3: Degree distributions for networks constructed in Simulations 2 and 3. All are on the same axes.

4544 words drawn at random from those occurring at least 10 times in the TASA corpus ($n = 164401$). Both matrices used the same 5000 random documents. For each matrix, 100 samples were taken with $T = 50, 100, 150, 200$ and 250. Since the results seemed unaffected by the number of topics, we will focus on $T = 50, 150, 250$. Ten samples were obtained in each of 10 separate runs with a burn-in of 1000 iterations in which no samples were drawn, and a between-sample lag of 100 iterations.

For each sample, a bipartite semantic network was constructed by connecting words to the topics to which they were assigned. For each network, the degree of each word node was averaged over the 100 samples.⁴ The resulting distributions were clearly power-law, as shown in Figure 3. The γ coefficients remained within a small range and were all close to $\gamma = -3.65$ for Roget's Thesaurus. As is to be expected, the average degree increased as more topics were made available, and was generally higher than Roget's. Semantic networks in which edges are added for each assignment tend to be quite densely connected. Sparser networks can be produced by setting a more conservative threshold for the inclusion of an edge, such as multiple assignments of a word to a topic, or exceeding some baseline probability in the distribution represented by that topic.

Our probabilistic approach produces power law degree distributions, in this case indicating that the number of topics to which a word is assigned follows a power law. This result is very similar to the properties of Roget's Thesaurus and Zipf's observations about dictionary definitions. This provides an op-

portunity to establish the origin of this distribution, to see whether it is a consequence of the modeling approach or a basic property of language.

Simulation 3: Origins of the power law

To investigate the origins of the power law, we first established that our initialization procedure was not responsible for our results. Using $T = 150$ and the matrix with random words, we obtained 100 samples of the degree distribution immediately following initialization. As can be seen in Figure 3, this produced a curved log-log plot and higher values of γ and $\langle k \rangle$ than in Simulation 2.

The remaining analyses employed variants of this co-occurrence matrix, and their results are also presented in Figure 3. The first variant kept word frequency constant, but assigned instances of words to documents at random, disrupting the co-occurrence structure. Interestingly, this appeared to have only a weak effect on the results, although the curvature of the resulting plot did increase. The second variant forced the frequencies of all words to be as close as possible to the median frequency. This was done by dividing all entries in the matrix by the frequency of that word, multiplying by the median frequency, and rounding to the nearest integer. The total number of instances in the resulting matrix was $n = 156891$. This manipulation reduced the average density in the resulting graph considerably, but the distribution still appeared to follow a power law. The third variant held the number of documents in which a word participated constant. Word frequencies were only weakly affected by this manipulation, which spread the instances of each word uniformly over the top five documents in which it occurred

⁴Since power law distributions can be produced by averaging exponentials, we also inspected individual samples to confirm that they had the same characteristics.

and then rounded up to the nearest integer, giving $n = 174615$. Five was the median number of documents in which words occurred, and documents were chosen at random for words below the median. This manipulation had a strong effect on the degree distribution, which was no longer power law, or even monotonically decreasing.

The distribution of the number of topics in which a word participates was strongly affected by the distribution of the number of documents in which a word occurs. Examination of the latter distribution in the TASA corpus revealed that it follows a power law. Our approach produces a power law degree distribution because it accurately captures the natural statistics of these data, even as it constructs a lower-dimensional representation.

General Discussion

We have taken a probabilistic approach to the problem of semantic representation, motivated by considering the function of associative semantic memory. We assume a generative model where the words that occur in each context are chosen from a small number of topics. This approach produces a lower-dimensional representation of a word-document co-occurrence matrix, and explicitly models the frequencies in that matrix as probability distributions. Simulation 1 showed that our approach could extract coherent topics, and naturally deal with issues like polysemy and asymmetries that are hard to account for in spatial representations. In Simulation 2, we showed that this probabilistic approach was also capable of producing representations with a large-scale structure consistent with semantic networks constructed from human data. In particular, the number of topics to which a word was assigned followed a power law distribution, as in Roget's (1911) Thesaurus and Zipf's (1965) law of meaning. In Simulation 3, we discovered that the only manipulation that would remove the power law was altering the number of documents in which words participate, which follows a power law distribution itself.

Steyvers and Tenenbaum (submitted) suggested that power law distributions in language might be traced to some kind of growth process. Our results indicate that this growth process need not be a part of the learning algorithm, if the algorithm is faithful to the statistics of the data. While we were able to establish the origins of the power law distribution in our model, the growth processes described by Steyvers and Tenenbaum might contribute to understanding the origins of the power law distribution in dictionary meanings, thesaurus topics, and the number of documents in which words participate.

The representation learned by our probabilistic approach is not explicitly a representation of words, in which each word might be described by some set of features. Instead, it is a representation of the probabilistic relationships between words, as expressed

by their probabilities of arising in different contexts. We can easily compute important statistical quantities from this representation, such as $P(w_2|w_1)$, the probability of w_2 arising in a particular context given that w_1 was observed, and more complicated conditional probabilities. One advantage of an explicitly probabilistic representation is that we gain the opportunity to incorporate this representation into other probabilistic models. In particular, we see great potential for using this kind of representation in understanding the broader phenomena of human memory.

Strategic Differences in the Coordination of Different Views of Space

Abstract

Participants were trained to use one of two different strategies in an orientation task, which were based on verbal reports from participants in another experiment. The data provide support for the conclusion that participants in the two training conditions searched the screen differently to complete the task, but that neither group used mental transformations like image rotation. These results have implications for research in this area as well as for conceptualizing how individuals perform such tasks. A comparison of the results from the two strategy conditions is made based on an ACT-R model of one of them. Small differences in how information on the screen is scanned can produce the observed differences in performance.

Introduction

The coordination of different views of space is a fundamental task in human functioning. An everyday example of it involves determining which way to turn at an intersection by using a map. The visual scene presents one view of the space (egocentric), while the map presents an alternative representation (allocentric). In order to accurately decide which way to go, it is necessary to bring these two views of the space into correspondence. Of course, with a physical map it may be possible to actually rotate it to align it with your own orientation. In other situations, mental transformations may need to be done in order to coordinate these views to make accurate decisions.

On a continuum of reasoning about orientation within a space, deciding whether the correct turn is left or right is a fairly straightforward task. Still, research on this issue has shown that it becomes increasingly difficult to perform as a function of the difference in orientation between the two views of space (Shepard and Hurwitz, 1984). The phenomenon bears a strong resemblance to findings in the mental rotation literature (Shepard and Metzler, 1971) where the time needed to determine that two objects are identical increases linearly as a function of the angular disparity between them. These findings have been used to support the conclusion that performance in orientation tasks involves analog mental rotation of mental images. Note, however, that the task

of coordinating views of space adds a layer of complexity to the traditional mental rotation task. In a spatial orientation task, the information is presented in two different formats. Thus, deciding whether the visual scene matches the information on the map requires additional reasoning beyond the image transformation.

In an important series of experiments, Hintzman, O'Dell, and Arndt (1981) had participants perform orientation tasks in a variety of ways. In the basic task, participants had to indicate the direction of a target relative to a given orientation. Figure 1 shows the orientation task used in the experiment presented here. In this figure, the left side represents the target field as viewed from a camera (on a plane above the field) and the darkened circle indicates the target. The right side represents a map-view with the target field at the center. The arrow on that side shows the camera's orientation for viewing the target field. Participants are asked to indicate in which cardinal direction the target is located relative to the center of the target field. In the sample trial in Figure 1, the correct response is South. The general finding is that decisions for targets in line with the assumed orientation are made more rapidly, and response times for other targets increase as they depart from the nearest point immediately in front of the viewpoint. Although not explicitly addressed by Hintzman, et al., this increase in response time is not strictly linear. In addition, no evidence was presented in their study about how participants claimed to be performing the task.

In order to investigate what factors influence performance on this task, we asked participants to complete the task and then questioned them as to the manner in which they solved it. While we will not go into detail about this experiment, the data are presented below and bear a strong resemblance to results from similar studies, including Hintzman, et al. (1981). However, by questioning participants after they had completed the experiment, we discovered that participants were using at least two distinct strategies to do the task. Some participants claimed to be implementing a strategy that incorporated imagery and mental rotation to determine correct responses.

However, other participants indicated that they used a different strategy altogether, one that did not depend on mental imagery or mental rotation at all.

Figure 1: Sample trial for the orientation task.

In the imagery-based strategy, participants reported forming an angle connecting the camera to the target in the camera view with the vertex at the center of the target field (a 135 degree angle in Figure 1). This angle was then mentally transformed to line it up with the position of the camera on the map view. A second group of the participants simply counted around the target field to the target on the camera view (3 in Figure 1), and then counted that number of steps from the camera's position in the appropriate direction on the map view.

Both strategies are equally effective and valid for doing the task, but one depends on mental imagery while the other does not. In addition, the verbal reports indicate that few of the participants treated the task as an orientation task. Rather, the strategies they reported suggest that they treated the task more like a traditional mental rotation experiment. That is, participants effectively eliminated the added level of complexity introduced by having different representations of the information by selecting strategies that bypassed the need to consider them. This finding casts some doubt on some previous explanations for performance on similar tasks. The experiment presented in detail below was conducted to further investigate the implications of these strategies, by training participants to perform the task using either the imagery-based "angle" strategy or the more analytic "counting" strategy.

Experiment

Previous research aimed at addressing performance on tasks similar to the one presented here have based explanations largely on mental imagery and mental rotation (Shepard and Hurwitz, 1984; Hintzman, et al., 1981), though Hintzman et al. do consider a sequential

scanning explanation. However, all these explanations fail to account for some of the more subtle aspects of the data and ignore the potential for different approaches to the task. The experiment presented here examines strategic differences in an orientation task that is similar to those used by Hintzman, et al (1981).

If the strategies were to be implemented according to the descriptions provided to participants, there should be clear differences in performance between the two strategy conditions. For the counting strategy, the position of the target relative to the camera should greatly influence response times. That is, response time should increase linearly as a function of the amount of the counting that needs to be done. However, the location of the camera in the map view should have no impact on performance, since the strategy can be implemented identically regardless of the camera's position in the map view. The angle strategy makes the opposite set of predictions. Response time should be unaffected by the target's location, since the angle to be formed is similar in complexity regardless of the target's position in the camera view. However, the degree of rotation that needs to be done depends on the camera's position in the map view, suggesting that response times should increase linearly as a function of the camera's position relative to the bottom of the screen.

Method

The experimental task was based both on the experimental task used by Hintzman, et al (1981) as well as on an unmanned air vehicle (UAV) flight simulator used by the Air Force for training UAV pilots (see Gugerty, et al, 2000; Figure 1). The display consisted of two static views, an egocentric "camera" view of a target field, and an allocentric "map" view. The target field was in the center of the map view, and the perspective of the camera was identified with an arrow (the right half of Figure 1). The target field was a circle, containing eight objects equally spaced at 45 degree intervals on the circle (the left portion of Figure 1), with one of them highlighted in red to identify it as the target. Participants were asked to indicate in which cardinal direction the target was located relative to the target field's center. Responses were made using the number pad on the keyboard.

After being introduced to the experimental task, participants were trained to complete the task using either the angle or counting strategy ($n=16$ per condition). They first read a brief description of the strategy, and then were shown how the strategy applied to a sample trial. After that, participants completed 16 paper-based practice trials in random order. In these practice trials, participants were asked to explicitly demonstrate use of the strategy they had been taught by labeling them appropriately based on the strategy they

had been taught. In the counting strategy condition, participants were taught to use positive numbers for targets on the left (clockwise from the camera), and negative numbers for targets on the right (counterclockwise). Participants in angle strategy condition were instructed to note the direction in which the angle "opened". Feedback was given on each of the practice trials by the experimenter.

After training, participants completed 4 blocks of trials on the computer. Each block included all 64 possible trials in random order. A dropout procedure was used such that if an error was made on one of the trials it was presented again later in the block. During this phase of the experiment feedback was still given after each trial, including what the correct answer was in cases where participants made an error.

Results

The results for the original experiment and the two training conditions in this experiment are presented in Figures 2 and 3. In Figure 2, response time is plotted as a function of the target's clockwise deviation from the camera. The numbers correspond to the measure of the clockwise arc from the camera position to the target on the target field in the camera view. In Figure 3, the data are presented as a function of the location of the camera relative to the target field in the map view. In the sample trial shown in Figure 1, the target angle is 135 and the camera's location is NE. One aspect of the data that should be immediately apparent from these graphs is that performance was symmetrical in terms of left and right positions of both the camera and the target. In addition, response times were somewhat faster in this experiment than in the first one. This may be a result of the training given in this experiment, which participants in the first experiment did not receive.

Finally, the training conditions used in this experiment seem to separate out two components of the data from the first experiment in terms of the effect of the target's position. Specifically, data produced by participants using the counting strategy increase linearly with the target's angular deviation from the camera. In contrast, the data produced by participants using the angle strategy show a scalloped effect, with no difference between 45 and 90 degrees (or 315 and 270 degrees). The data from the original experiment show evidence of a combination of both trends. This suggests that averaging data over all participants may not provide a complete story of the effects in this task.

At the highest level of abstraction, there was no main effect of strategy condition in average response time, $F(1,210)=0.233, p=.63$, suggesting that at a global level both strategies were equally effective for completing the task. One has to be struck by the overall similarity of the results between the two strategy conditions and their close relation to the results from the first study,

given that participants were taught quite different ways of doing the task. Despite the overall similarity, there was a significant interaction between the strategies and the particular target angle, $F(7,210)=3.534, p<.02$, as well as between the strategies and the camera angle, $F(7,210)=3.810, p=.01$. Looking at Figure 2, response times were higher for participants using the angle strategy when the target was directly in front of the camera or when it was 45 degrees to the right or left. In terms of camera angle, Figure 3 shows that participants trained to use the angle strategy exhibit relatively longer latencies when the camera is located in a northerly position.

Figure 2: Response time (sec) as a function of the target's position.

Figure 3: Response time (sec) as a function of the camera's position.

Discussion

Based upon the data, it is clear that participants were not executing the strategies precisely according to the instructions provided. In fact, only one of the predictions is clearly borne out in the data. Specifically, response times increased linearly as a function of the extent of counting for participants trained to use the counting strategy. However, these participants still

showed a small effect of the camera's location. In addition, data from participants trained to use the angle strategy showed a discontinuous effect of both the camera's position and the target's relative position.

The most curious result is the effect of the target's position relative to the camera in the angle strategy. That is, the description of the angle strategy predicts no increase in response time as a function of the target's location. However, an increase does occur, and it is complicated by the discontinuity at 90 and 270 degrees. This finding, in particular, casts doubt on the claim that participants were using mental rotation at all in performing this task. In particular, it is hard to imagine how an imagery-based strategy can account for this particular effect without resorting to specialized mechanisms relating to imagining and/or manipulating 90-degree angles. Research does suggest that cognitive representations of space tend to distort angles to be closer to 90 degrees (Glicksohn, 1984), and also indicates that horizontal and vertical lines are preferred in visual perception (45 and 135 degree angles involve oblique angles; Cecala and Garner, 1986). Still, it is not clear how this should have such a large impact on the ability to manipulate or create mental images of angles of various sizes. A more likely explanation is that the differences in performance between the two strategy conditions arise from small differences in how the screen was scanned by participants as a result of their training, rather than because of differences in higher-level cognitive operations on the information.

In the counting strategy, the linearity of the target-position effect suggests that participants were indeed counting from the camera's position to find the target. The small effect of the camera's position, however, indicates that the strategy was not being implemented exactly according to the instructions. We believe that participants encoded the location of the target as being to the "left" or "right" of the camera, rather than as "clockwise" or "counterclockwise". While this is a small difference in encoding, it does have implications for locating the target on the map view. If a target location is encoded as clockwise, the map view can be scanned in a clockwise direction regardless of where the camera is located. However, if the location of the target is represented as "left" instead, the correct scanning direction is "right" when scanning from NW, N, or NE. So, whenever participants search the screen from one of these locations, extra cognitive steps are needed to make sure that the screen is scanned in the appropriate direction.

An example should clarify how we believe the counting strategy was implemented by participants. For this purpose, consider the trial presented in Figure 1. We believe that counting participants would begin this trial by locating the target on the camera view and encoding it as "3-left". At that point, they would find

the camera's location on the map view. Since the camera is located at NE, the correct search direction is actually "right", so an extra operation is needed to convert the direction of scanning. Then, the screen can be scanned to locate East, and the count can then be incremented. Then, Southeast can be found, and the count incremented again, followed by South and the final increment in the count sequence. At this point, participants have located the answer and can issue their response by pressing the "2" key on the number pad (keys were assigned to correspond to the layout of cardinal locations on the screen).

Given that participants using this strategy produced data that were largely in line with predictions and the results were similar to the other condition, we decided to develop a model for the counting strategy. This is a first step to an overall model for the task, which will involve some mixture of strategies.

ACT-R Model

The ACT-R theory (Anderson and Lebiere, 1998) provides an architecture in which the proposed mechanisms can be implemented to determine how well they fit with the data. In addition, ACT-R now incorporates a theory of perceptual-motor action, allowing it to interact directly with the experimental software (Byrne and Anderson, 1998). In this way, an ACT-R model can participate in the experiment exactly as though it were a participant by gathering information from the screen using visual perception, operating on that information within its cognitive system, and issuing a response by sending commands to its motor module. This integration means that all aspects of performance are considered in the model's performance.

Model Design

There is certainly a large degree of overlap between the two strategy conditions. In particular, the details of gathering information and issuing responses in the task are assumed to be largely the same for both strategies. Thus, by understanding how participants executed one of the strategies it will be easier to understand how participants in the other condition may have performed the task. Toward that end, a model of the counting strategy has been implemented and is described next. In the conclusion, we will describe how we believe the behavior of participants trained to use the angle strategy may have differed to produce the observed results.

When a new trial is presented to the model, its first action is to search for the location of a red object on the left side of the screen. Its location is encoded as being left or right of the camera and as an integer value from 0 to 4 to define its distance from the camera. Then, the model finds the location of the camera on the map view and shifts its attention to that location.

Since it is hypothesized that the location of the target is encoded as left or right rather than clockwise or counterclockwise, the model needs to alter its scanning direction when the camera is in the NW, N, or NE positions. Once the appropriate scanning direction is selected, the model finds the nearest cardinal direction to the camera and increments its count. This process is repeated until it has incremented the count the prescribed number of times. At that point, the current cardinal location is encoded and mapped to a response on the number pad. Finally, the model issues a response by sending a command to press the correct key.

Based on verbal reports from participants, there were a couple of exceptions to this operation. First, when the target was located in line with the camera, participants reported that they did not bother to count. Rather, for target positions of 0 degrees they simply responded with whatever position the camera was in, and for target positions of 180 degrees they responded with the cardinal direction directly opposite the camera's position. The other instance where the strategies were not used was when the position of the camera was S. In this case, participants reported that they went directly from the target's location on the camera view to a response. In response to these verbal reports, these special cases were implemented in the model. These reports also correspond to data presented in previous studies (e.g., Hintzman, et al., 1981).

Model Performance

The model's performance using the counting strategy compared to the data in the two conditions is presented in Figure 4. As can be seen, it makes accurate predictions for response times for both conditions in both aggregations of the data (correlation = .98, mean deviation = .11 seconds). The model performs the task in exactly the way we believe participants are doing the task. That is, the model incorporates all of the perceptual, motor, and cognitive steps that humans would need to go through to do the task. Based on this completeness, we feel that the model captures all of the relevant aspects of participant performance.

The linear increase in response time as a function of target location is produced in the model by the simple act of counting and scanning cardinal locations sequentially. For target angles of 45 and 315 degrees, one step is counted, for 90 and 270 degrees this is done twice, and for 135 and 225 degrees there are three cycles. The small effect of the camera's position results from the left/right encoding of the target position. As described above, this creates the need to perform extra cognitive operations to switch the scanning direction at any point when searching from NW, N, and NE, thus increasing response times in trials where those situations arise. This evaluation occurs at each step in the search process. So, each time the model searches for

the next cardinal location, it determines whether or not the encoded direction of the target is the correct search direction, and then alters the search direction when necessary.

Figure 4. performance of the model of the counting strategy compared to participants' data.

In terms of the overall qualitative pattern of data, the performance of the model is parameter-free. By constructing a model that really does the task, its performance is highly constrained at this level. The parameters serve only to adjust the magnitude of the effects. First, retrievals from memory are an important aspect of the model's operation. The model retrieves various facts from memory as it performs the task, including counting sequences for the counting process, associations between cardinal directions and number keys for making responses, and information about cardinal directions for guiding the search and problem solving process. In this model, the time to perform these retrievals was set to .05 (seconds). The only other parameter that was explicitly set in this model is the execution time for the production that encodes the target's location on the camera view. This value was set to .7 (seconds) and impacts all conditions similarly. The remaining parameters all reflect default perceptual-motor parameters in ACT-R/PM (Byrne and Anderson, 1998). The model's source code is available online at <http://act.psy.cmu.edu/>.

Conclusions

The experiment and model presented here provide an alternative view of findings in the area of spatial cognition concerning how participants perform orientation tasks. There are two basic questions to answer. First, are participants actually performing an orientation task in these studies? The participants in this experiment were clearly not treating this task as a traditional orientation task where two distinct representations of spatial information are brought into correspondence. Rather, much of the complexity was

eliminated by implementing strategies that avoided this aspect of the task. It is unclear whether similar strategic choices can achieve the same effect in more realistic orientation tasks (e.g., Gugerty, et al., 2000).

The other basic question to ask based upon these results is whether participants use mental imagery in performing the task. If they do, it is important to investigate how such cognitive abilities are applied in these tasks. If not, the question becomes what mechanisms are responsible for participant performance on these sorts of tasks. Based on the data presented here, it appears that participants assumed a more analytic approach to the task, simply scanning the screen in a systematic way to determine the correct answer. These findings also illustrate that there is variability in how participants approach virtually any task, and these variations have implications for performance.

The model shows that we can reproduce much of the qualitative form of the results in this task by implementing a strategy that involves systematically scanning the information on the screen. Moreover, this strategy corresponds to what some participants spontaneously report. However, what about the other participants who spontaneously report an angle strategy? We believe that they may be just engaging in a variant of the implemented scanning strategy, which explains why their behavior is so similar to the participants who were counting. More specifically, we believe that implementing the angle strategy involves such differences as looking at more of the information on the camera view but not systematically looking at the intermediate points between the camera and target on the map view. Both of these differences could be produced by the different training conditions in the experiment. We are currently implementing a model which incorporates such a variant of the scanning strategy and doing an eye movement study to see if we can find evidence for the hypothesized scanning patterns.

Basically our proposal is that participants prefer to process the information given on the screen rather than transform an internal image of this information. This aversion for mental transformations is consistent with the results of Kirsh & Maglio (1994) who found that people prefer to rotate objects on the Tetris screen rather than rotate them in their head. We suggest that some results attributed to mental rotation like those in this task may reflect the operation of some other process like the scanning in the counting strategy that we have implemented. While Hintzman, et al. (1981) considered sequential scanning as an alternative explanation to mental rotation, they did not consider the possibility of strategic differences in the scanning process. The results presented here demonstrate that such strategic differences exist and that some scanning

strategies can result in data that approximately match predictions based on imagery and mental rotation. In addition, participants trained to use mental imagery produced data that does not fit with the imagery account. An evaluation of the model for the counting strategy suggests that small differences in encoding and visual scanning can account for the differences found in the angle strategy. These findings suggest that mental rotation may not provide a full account of human performance in orientation tasks.

Abstract

Classical choice theories assume choice behavior is based on value maximization computed over the entire choice set. However, empirical evidence has revealed violations of axioms of rational choice that cannot be explained by value maximization. We argue that choice behavior can be reconceptualized as value maximization constrained by categorization processes, and describe a neural network model developed to account for key empirical findings. The model simulates two important phenomena that have been construed as irrational choice behavior, namely, the similarity effect and the attraction effect. We argue that there are important commonalities among choice behavior, categorization and perception.

Introduction

Many axiomatic theories of choice behavior are based on the assumption that decision making is based on a process of value maximization performed over all attributes (c. f., Tversky & Simonson, 1993). However, empirical evidence has demonstrated that axioms of rational decision making are often violated in choice behavior, and value maximization alone is unable to explain these violations. Recently, an alternative perspective that is concerned with the relations between similarity processes and decision processes has been proposed to conceptualize choice behavior and to understand violations of rational decision making (Medin, Goldstone, & Markman, 1995). That view has been embodied in a comprehensive computational model of choice behavior (Roe, Busemeyer, & Townsend, 2001).

In the spirit of this alternative perspective, we have developed a connectionist model to account for two key violations of rational choice, namely, the similarity effect and the attraction effect. Both of these phenomena involve adding a third alternative (decoy) to a choice set of two options, thereby leading to inconsistency of choice. If the decoy is similar and competitive (two alternatives are competitive when their additive utilities are almost identical to each other) to one of the original options, then the addition of the decoy decreases the choice probability of that option. This phenomenon is called

the similarity effect (Tversky, 1972). If the decoy is similar to and dominated by one of the two original alternatives but not the other, then the addition of the decoy increases the choice probability of the dominant option more than the other alternative. This phenomenon is referred to as the attraction effect (Huber, Payne, & Puto, 1982). Both phenomena can potentially lead to violations of rational choice. Few theories were able to provide an integrated explanation of both phenomena prior to the model proposed by Roe et al. (2001), which is a neural network instantiation of the decision field theory (Busemeyer & Townsend, 1993). That model explains the two effects (in addition to several other important choice phenomena) by taking into consideration similarity relations among options and the dynamic nature of decision processes. The model described here is similar to that of Roe et al. in that it also takes into account similarity among alternatives; however, the manner in which similarity is represented and processed differs between the two models. We will briefly discuss the relationship between the two models after we present our proposal.

Neural network models have been one of the major modeling tools in cognitive science (Rumelhart, McClelland, & PDP Research Group, 1986). However, such models have had only limited applications to decision behavior (Holyoak & Simon, 1999; Roe et al., 2001; Thagard & Millgram, 1995). The model we describe here, like that of Roe et al. (2001), uses a neural network approach to provide an account of the similarity and attraction effects.

Operation of the Model

Decision Scenario and Model Architecture

The decision scenario used here is adapted from that used by Roe et al. (2001). The decision maker has to choose one car from a set of two or three alternatives by evaluating their ratings on two attributes: gas mileage and performance (see Figure 2). A simple neural network is constructed for this scenario. Figure 2 shows the architecture of the model, adapted from ECHO (Thagard, 1989), a neural network

model of how people achieve coherence in making explanations. Two nodes represent the attributes, gas mileage and performance, and three others represent the three alternatives. One special node, labeled as External Driver in Figure 2, represents the motivational and attentional sources that drive the decision process. The lines between nodes represent node connections. Each attribute or alternative is thus represented by one node in the network, with relations among attributes and alternatives represented by connection weights.

Bidirectional excitatory links (represented by dark arrowheads in Figure 2) connect attribute nodes to their respective alternatives. The alternative nodes send out inhibitory influences (represented by empty arrowheads in Figure 2) to one another. Node activation ranges from 0.0 to 1.0. The special node, which drives the decision-making process, always feeds excitatory influence to the attribute nodes, thereby initiating and maintaining activation throughout the entire network. The special node has a constant activation of 1.0, and the weight of its connections to the attribute nodes is 0.05 (there are no reciprocal connections to the special node from the attribute nodes, as the former is intended to be the source of activation). Because the three alternative nodes compete via inhibitory connections with one another, one winning node generally achieves a much higher activation than the rest.

Setting Connection Weights and Initial Activations

Initially, the connection weight between an attribute and an alternative node (called *attribute-alternative weight* from now on) is set to the rating of the alternative on the corresponding attribute. For example, in Figure 2, the option Target is rated 8 and 2 on performance and gas mileage, respectively, so its initial weights are set to 8.0 and 2.0 for the performance-target and gas-mileage-target connections, respectively.

Next, each initial weight is normalized:

$$w_{ij} = \eta + \frac{(w_{ij} - \min(w)) \cdot (\kappa - \eta)}{\max(w) - \min(w)}. \quad (1)$$

Here, w_{ij} is the weight of the connection to node i from j . Weights are normalized according to their range; κ and η are maximum (set to 0.8) and minimum (set to 0.2) values for that range, respectively. Accordingly, the normalized weight

Figure 1. A summary of the phenomena simulated. The letters S and A stand for where the decoy is positioned: Decoy S yields the similarity effect; decoy A yields the attraction effect. The numbers in parentheses are the attribute ratings of the nearby alternative: The first number is the rating of that alternative on gas mileage and the second number is its rating on performance.

Figure 2: The architecture of the model. Choice 1, Choice 2 and Choice 3 are the alternatives, and Gas Mileage and Performance are the attributes. External Driver represents the motivational and attentional sources that drive the decision process.

should always be within the range of 0.2 to 0.8. The choice of this range is arbitrary, but it reflects the

assumption that the perception of an attribute value should never actually reach 0, which can be viewed as reflecting no value at all, nor should it reach 1, which can be viewed as reflecting sublime satisfaction. The range of actual attribute value is computed by $\max(w) - \min(w)$, where $\max(w)$ and $\min(w)$ are the largest and smallest attribute values obtained for all attributes.

The attribute-alternative weights as defined in Equation 1 are linearly related to the actual attribute ratings. In choice behavior, we are concerned with a *subjective* measure of utility in which the impact of a given increase in rating declines with the absolute magnitude of the rating. Accordingly, attribute-alternative weights are transformed:

$$w_{ij} = \frac{w_{ij} l}{w_{ij} + \lambda} \quad (2)$$

Here, both l and λ are constants. After exploration of the parameter space, l was set to 1.4 and λ was set to 0.5 to achieve good simulation results. Equation 2 describes a basic psychophysical function in which sensitivity to an increase of stimulus strength declines as the stimulus strength increases. Finally, weights undergo a linear transformation specified by

$$w_{ij} = w_{ij} \tau / 10.0. \quad (3)$$

Here, τ (set to 4.0) is a parameter intended to amplify the attribute-alternative weights so that the same difference between attribute values now has a larger impact on node activations (see Equations 4 and 5). Finally, these weights are divided by 10.0 so that they are kept reasonably small in relation to node activations. Although the model has several parameters, and specific values for them were selected after extensive search of parameter space, the choices of parameter values do not affect the underlying conceptual framework of the model. Moreover, it is very likely that other sets of parameter values exist that would allow the model to exhibit desired behavior.

The inhibitory connections among the alternative nodes are all set to -0.60. The initial activations are set to 1.0 for the special node and 0.5 for all other nodes (0.5 is the middle point of the activation range, 0.0 - 1.0). To increase psychological realism, some randomness is introduced: The initial activation of an alternative node is a random number within the range of 0.5 ± 0.01 . The generation of random numbers conforms to a uniform distribution. There is no randomness for the activations of the special node and the attribute nodes.

Running the Model

The model runs in an iterative fashion. In each iteration the activation of a node is updated by a commonly-used activation function,

$$a_i(t+1) = \begin{cases} input_i(MAX - a_i(t))\gamma + a_i(t)(1 - \theta) & \text{if } input_i > 0 \\ input_i(a_i(t) - MIN)\gamma + a_i(t)(1 - \theta) & \text{otherwise} \end{cases} \quad (4)$$

$a_i(t+1)$ is the activation of node i at iteration $t + 1$; it is a function of $a_i(t)$, the activation of the same node at the previous iteration. MAX and MIN are the upper (1.0) and lower (0.0) limits of node activation. θ (set to 0.015) is a decay parameter specifying how much the activation decays in each iteration, and γ (set to 0.12) is a growth rate specifying the increment of activation as a function of the input. The parameter $input_i$ is the total influence received by node i from other nodes connected to it, specified by

$$input_i(t) = \sum_j w_{ij} a_j(t). \quad (5)$$

The model runs iteratively according to Equations 4 and 5 until the activation of each node no longer changes from the previous iteration by more than a settling criterion (set to 0.001 here). According to Equation 4, a major determinant of node activation is the total input a node receives from other nodes; and according to Equation 5, this input depends on the attribute-alternative weights. It follows that an alternative with a high additive attribute rating tends to have a higher node activation than those with low additive attribute ratings; this is an instantiation of the value maximization principle, which implies that the winning choice should have the highest additive utility summed across all attributes.

The choice probability of an alternative depends on the activation of the corresponding node. Luce's (1959) choice model is used to convert the activation into choice probability for alternative i :

$$probability(i) = \frac{activation(i)}{\sum_j activation(j)} \quad (6)$$

Simulations and Results

The two phenomena simulated are schematized in Figure 1. For each phenomenon, 100 simulations were run and the results were averaged for each attribute and alternative. The averaged results are presented both as node activations, which are the final activation values of the nodes (see Table 1), and

choice probabilities, which are converted from activations using Equation 6 (see Table 2).

Figure 3: Decision process of binary choice. The activation of alternative nodes is plotted as a function of number of iterations.

Binary Choice

The original choice set contains two alternatives, one of which is arbitrarily selected as the target, and the other the competitor (see Figure 1). Both cars receive ratings on a 10-point (1 - 10) scale for gas mileage and performance. To simplify the choice scenario, the two options are made equal in terms of additive attribute rating: The competitor is rated 8 on gas mileage and 2 on performance, whereas the target is rated 2 on gas mileage and 8 on performance. It is a trivial prediction that (assuming the two attributes are equally important) the two alternatives should be equally likely to be chosen. The model makes this prediction: when these two alternatives are equally attractive, both have a 50% chance of being chosen (see Table 2).

Similarity Effect

If the decoy is similar and competitive compared to one of the two original choices, the target, the introduction of the decoy reduces the probability of

the target being chosen relative to that of the other choice in the original set, the competitor. This similarity effect (Tversky, 1972) can lead to a violation of an axiom of rational choice, independence of irrelevant alternatives, which implies that adding an alternative to a choice set will not alter the rank order of the original options. To produce a similarity effect, the decoy should be roughly as good as the target in terms of additive attribute rating. In the simulation, the decoy is chosen to have attribute values of 2.5 and 6.5 for gas mileage and performance, respectively (see Figure 1).

To model the similarity effect, we first run the model on a choice set that includes only the target and the decoy. After the network settles for that comparison, we run it on the entire set of three alternatives. The psychological rationale is that because the target and the decoy are similar to each other, they are grouped together in a manner similar to a perceptual grouping (e.g., in visual perception, when two shapes are close to each other, they are perceived as belonging to the same cluster). Our assumption is that the two similar alternatives are perceived as belonging to the same category, and therefore are compared to each other before all three alternatives are compared.

The simulation was thus divided into two stages: a binary comparison in which only the target and the decoy were compared, and a trinary comparison in which all three alternatives were compared. The activations are carried over from the first to the second stage; accordingly, any activation differences from the first stage will have an effect on the second stage. At the end of the binary-comparison stage, the target has an activation lower than 0.5, the baseline activation, due to its competition with the decoy. This low activation is carried over to the trinary-comparison stage, where the competitor joins the comparison with the default initial activation of 0.5. Thus in the trinary-comparison stage the target starts with a lower activation as compared to the competitor; as a result, the target attains a lower activation and choice probability as compared to the

Table 1: Simulation results as node activations.

Choice scenarios	average node activations				
	gas mileage	performance	competitor	target	decoy
Binary choice	0.647	0.647	0.398	0.398	-----
Similarity effect	0.695	0.729	0.424	0.343	0.317
Attraction effect	0.708	0.741	0.465	0.627	0.019

Note. Each node activation displayed here is the average of activations for the corresponding node calculated over 100 simulation runs.

competitor at the end of simulation. The dynamic process of the two-stage comparison is shown in Figure 4, where the sudden change in activation indicates the transition from the first to the second stage. The final choice probabilities of the target and the competitor are 0.317 and 0.391 respectively (see Table 2), indicating that the competitor ranks higher in terms of preference. Since in the binary choice the choice probabilities of the two alternatives are equal, the altered rank order is a violation of the principle of independence of irrelevant alternatives.

Table 2 Simulation results as choice probabilities.

Choice scenarios	average choice probabilities		
	competitor	target	decoy
Binary choice	0.500	0.500	----
Similarity effect	0.391	0.317	0.292
Attraction effect	0.419	0.564	0.017

Note. Each choice probability displayed here is the average of choice probabilities for the corresponding node calculated over 100 simulation runs.

Attraction Effect

Huber et al. (1982) showed that when the additional alternative (a dominated decoy) is similar to and obviously inferior to one of the alternatives (the target) of the original choice set, the introduction of this decoy will increase the probability of the target being chosen more than that of the competitor. This effect can potentially increase the probability that the target is chosen, thereby leading to violation of an axiom of rational choice, the regularity principle, which states that adding additional alternatives into the choice set would not increase the choice probabilities of options in the original choice set (cf. Huber et al., 1982). The violation of the regularity principle is a stronger form of preference reversal than the violation of independence of irrelevant alternatives.

The same two-stage comparison is employed to model the attraction effect, because the target and the decoy are similar to each other and therefore form a natural grouping. At the end of the binary comparison, the target has an activation higher than 0.5, the baseline activation, due to its superiority as compared to the decoy. This advantage in activation is carried over to the trinary comparison, and as a result the target has a relatively high activation and choice probability at the end of the simulation run. The dynamic process of the two-stage comparison is shown in Figure 5, where the sudden change in

activation indicates the transition between the two stages of comparison. The final choice probability of the target is 0.564 (see Table 2). In the original binary choice set, the target has a choice probability of 0.5 (see Table 2); thus adding the decoy leads to a violation of regularity principle.

Figure 4: Decision process of similarity effect. Axes are the same as Figure 3. The vertical dashed line indicates the transition from binary comparison to trinary comparison.

Figure 5: Decision process of attraction effect. Axes are the same as Figure 3. The vertical dashed line indicates the transition from binary comparison to trinary comparison.

In simulating both effects, the model still computes a form of value maximization; however, the computation is carried out in a local instead of global manner during the first stage of comparison, due to the categorization process in which two similar alternatives are grouped and processed together independently of the third alternative.

Conclusions

The connectionist model presented here explains two perplexing empirical findings in choice behavior using a straightforward neural network algorithm and simple psychological principles. It has been argued that the principle of value maximization underlying rational choice is in conflict with some apparently irrational choice behaviors (Simonson & Tversky, 1992). However, the present model shows that choice behavior can be viewed as value maximization constrained by categorization processes.

Roe et al. (2001) also used similarity relations to account for the similarity and attraction effects. In their neural network model, lateral inhibition among alternatives is set in such a way that the more similar two options are, the stronger is the lateral inhibition between them. This differential inhibition provides a foundation for modeling similarity-related findings. In contrast, in the present model similarity is assumed to lead to a grouping effect, which in turn leads to the two-stage comparison process. Thus while both models emphasize the role of similarity in choice behavior, Roe et al.'s algorithm models the impact of similarity by variations in a continuous parameter for inhibition; whereas the present algorithm hold inhibition constant and instead assumes that similarity alters the grouping of options, leading to a multi-stage comparison process. Further empirical investigations will be required to distinguish between these two possible mechanisms by which similarity may modulate choice behavior.

The present model has several limitations that will need to be addressed in future work. For example, the choice scenario is constructed in a highly schematic way, and more complex and realistic choice scenarios need to be used in future studies. Also, the way the connection weights are set by explicit equations is rather artificial; future efforts need to address how the weights may be acquired using a connectionist learning mechanism. Perhaps most importantly, the critical assumption that similar choices are grouped together and therefore processed together in choice behavior requires further empirical investigation.

The present model may have implications for applied work. Expert systems based on the current model can be developed to analyze and predict choice behavior. In contrast to more traditional axiom-based systems, such systems may make it possible to analyze apparently irrational choice and decision processes, thereby leading to more accurate predictions of human decisions.

Abstract

How do people learn and organize examples in the absence of a teacher? This paper explores this question through an examination of human data and computational modeling results. The SUSTAIN (Supervised and Unsupervised STRatified Incremental Network) model successfully fits human learning data drawn from two published studies. The first study examines how correlations between features can facilitate unsupervised learning. The second set of studies examines the role that similarity and attention play in unsupervised category construction (i.e., sorting) tasks. Importantly, SUSTAIN suggests two novel behavioral predictions that are confirmed.

Introduction

The study of human category learning has focused on supervised learning. Researchers typically utilize a experimental procedure in which the participant must learn to classify a set of stimuli while receiving corrective feedback on every trial. Certainly, there are many other ways to learn about the world. Our environment does not always provide us with explicit feedback and thus, some learning is better characterized as unsupervised. For example, we routinely categorize incoming email as "junk mail" in the absence of a teacher. A great deal of human learning may be unsupervised. The goal of this paper is to expand our understanding of how humans learn from examples without supervision.

To achieve this goal, we fit the SUSTAIN model of category learning to Billman and Knutson's (1996) studies concerning how humans learn correlations through observation and to Medin, Wattenmaker, and Hampson's (1987) data on unsupervised category construction (i.e., sorting) behavior. SUSTAIN successfully accounts for human performance in both of these studies with one set of parameters. Importantly, SUSTAIN's account of these studies suggests novel predictions which are subsequently tested (and confirmed) with human subjects.

The Modeling Approach

SUSTAIN has been successfully applied to an array of challenging human data sets spanning a variety

of category learning paradigms including supervised classification (Love & Medin, 1998), inference learning (Love, Markman, & Yamauchi, 2000), and unsupervised learning (Gureckis & Love, 2002). One primary goal of our modeling approach is to address multiple forms of category learning (both supervised and unsupervised) with one consistent set of principles. After a brief introduction to the operation of SUSTAIN, these core principles will be discussed.

Introduction to SUSTAIN

SUSTAIN is a clustering model of human category learning. The internal representation of the model consists of a set of clusters. Category representations consist of one or more associated clusters. At the start of learning, the network has a single cluster that is centered in this representational space upon the first input pattern.

When a new stimulus item is presented, SUSTAIN attempts to assign the item to the most similar existing cluster. This assignment is unsupervised since it is based only on the similarity between item and cluster. If a *surprising* event occurs, such as a misprediction in supervised learning or a stimulus is encountered in unsupervised learning that is not similar to any existing cluster, SUSTAIN creates a new cluster to encode the current stimulus. This new cluster is centered in the representational space on the misclassified item.

When a stimulus is not surprising, the item is assigned to the most similar existing cluster and this cluster updates its internal representation to become more similar to the current item (a process somewhat analogous to prototype formation). Classification decisions are based on the cluster to which a stimulus instance is assigned. Like other models of category learning (e.g., Kruschke, 1992), SUSTAIN's selective attention mechanism learns to selectively weight stimulus feature dimensions that are most useful for categorization.

The Principles of SUSTAIN

With this general understanding of the operation of the model, we now examine the six key principles that underly SUSTAIN.

Principle 1, SUSTAIN is directed towards simple solutions SUSTAIN is initially directed towards simple solutions. At the start of learning, SUSTAIN has only one cluster which is centered on the first input item. It then adds clusters (i.e., complexity) only as needed to accurately describe the category structure of the learning task. Its selective attention mechanism further serves to bias SUSTAIN towards simple solutions by focusing the model on the stimulus dimensions that provide consistent information.

Principle 2, similar stimulus items tend to cluster together In learning to classify stimuli as members of two distinct categories, SUSTAIN will cluster similar items together. For example, different instances of a bird subtype (e.g., sparrows) could cluster together and form a sparrow cluster instead of leaving separate traces in memory for each instance. Clustering is an unsupervised process because cluster assignment is done on the basis of similarity, not feedback.

Principle 3, SUSTAIN relies on both unsupervised and supervised learning processes As discussed above, SUSTAIN can cluster based on similarity (an unsupervised process). SUSTAIN's operation is also affected by supervision (when available). Consider the example of SUSTAIN learning to classify stimuli as members of the category mammals or birds. Let's assume that a cluster representing four-legged, hairy, land creatures is already acquired, as well as another cluster representing small, winged, creatures that fly. The first time SUSTAIN is asked to classify a bat, the model will predict that a bat is a bird because the bat stimulus will be more similar to the existing bird cluster than to the existing mammal cluster. Upon receiving corrective feedback (supervision), SUSTAIN will note its error and create a new cluster to store the anomalous bat stimulus. Now, when this bat or one similar to it is presented to SUSTAIN, SUSTAIN will correctly predict that the bat is a mammal. This example also illustrates how SUSTAIN can entertain more complex solutions when necessary through cluster recruitment (see Principle 1).

Principle 4, Clusters are recruited in response to surprising events As the previous example illustrates, surprising events lead to new clusters being recruited. In unsupervised learning, a surprising event is simply exposure to a stimulus that is not sufficiently similar to any existing cluster (i.e., a very novel stimulus).

Principle 5, the pattern of feedback matters As the bird-mammal example above illustrates, feedback affects the inferred category structure. Prediction failures result in a cluster being recruited, thus different patterns of feedback can lead to different representations being acquired. This principle al-

lows SUSTAIN to predict different acquisition patterns for different learning modes (e.g., inference versus classification learning) that are informationally equivalent but differ in their pattern of feedback.

Principle 6, cluster competition Clusters can be seen as competing explanations of the input. The strength of the response from the winning cluster (the cluster the current stimulus is most similar to) is attenuated in the presence of other clusters that are somewhat similar to the current stimulus (compare to Sloman's, 1997, account of competing explanations in reasoning).

Model Fits and Predictions

In the following sections, Billman and Knutson's (1996) results are described, fit, and SUSTAIN's novel predictions are tested. Following Billman and Knutson, Medin et al.'s (1987) work is given similar consideration.

Modeling Billman and Knutson's (1996)

Billman and Knutson's experiments tested the prediction that category learning is easier when certain stimulus feature dimensions are predictive of other feature dimensions (e.g., "has wings", "can fly", "has feathers" are all inter-correlated features of birds) than when correlations are unrelated or are not numerous. Their studies evaluate how relations among stimulus feature dimensions affect learning in an unsupervised task. SUSTAIN has successfully fit Billman and Knutson's (1996) Experiment 2 and 3 (Gureckis & Love, 2002). Here, we focus on Experiment 3.

Fitting Billman and Knutson's (1996) data

Subjects studied stimulus items that depicted imaginary animals made up of seven feature dimensions: type of head, body, texture, tail, legs, habitat, and time of day pictured. Each dimension could take on one of three values. For example, the time of day could be "sunrise", "nighttime", or "midday". The correlational structure of the feature dimensions varied according to which of two conditions (either the Structured or the Orthogonal condition) the subject was randomly assigned. The abstract structure of the two conditions is shown in Table 1. In the Structured condition, the first three stimulus dimensions are intercorrelated (for a total of three correlations), while the remaining four dimensions vary freely. The Orthogonal condition's structure also contains three correlations (the first and second dimensions are correlated, as are the third and fourth, and the fifth and the sixth), but the correlations are isolated (e.g., the first and third dimension are not correlated).

In the learning phase for both conditions, subjects were told that they were participating in a visual memory experiment and viewed 27 stimulus items for four blocks (a block is a single pass through all training items). Each of the 27 items appeared once

Table 1: The logical structure of the stimulus items for the Orthogonal and Structured conditions in Experiment 3 of Billman and Knutson (1996). The seven columns denote the seven stimulus dimensions. Each dimension can display one of three different values, indicated by a 1, 2, or 3. An x indicates that the dimension was free to assume any of the three possible values.

Structured Condition								
1 1 1 x x x x			2 2 2 x x x x			3 3 3 x x x x		
Orthogonal Condition								
1 1 1 1 1 1 x			2 2 1 1 1 1 x			3 3 1 1 1 1 x		
1 1 1 1 2 2 x			2 2 1 1 2 2 x			3 3 1 1 2 2 x		
1 1 1 1 3 3 x			2 2 1 1 3 3 x			3 3 1 1 3 3 x		
1 1 2 2 1 1 x			2 2 2 2 1 1 x			3 3 2 2 1 1 x		
1 1 2 2 2 2 x			2 2 2 2 2 2 x			3 3 2 2 2 2 x		
1 1 2 2 3 3 x			2 2 2 2 3 3 x			3 3 2 2 3 3 x		
1 1 3 3 1 1 x			2 2 3 3 1 1 x			3 3 3 3 1 1 x		
1 1 3 3 2 2 x			2 2 3 3 2 2 x			3 3 3 3 2 2 x		
1 1 3 3 3 3 x			2 2 3 3 3 3 x			3 3 3 3 3 3 x		

per block in a random order. The only difference between the Structured and Orthogonal conditions was the abstract structure of the stimuli that were shown during the learning phase.

In the test phase of the experiment, subjects viewed a novel set of 54 stimulus pairs. Each member of the pair had two of the seven feature dimensions obscured (e.g., the locations where the tail and head should have been were blacked out) so that information about only one correlation was available for each item in test pair. One item in the pair preserved the studied correlation, while the other item violated the correlation. Subjects were asked to choose the stimulus item in the pair that seemed most similar to the items studied in the learning phase (a forced choice procedure). The item that preserved the studied correlation was considered the correct choice. For example, in the isolating condition the correct item of the pair might have the abstract structure [1 1 m 1 m 1 2] because it preserves the correlation between the first and second dimensions (the 'm' represents a dimension that was blocked). The incorrect item of the pair might then be [1 2 m 1 m 1 2] which breaks the correlation present in the training items between the first and second dimension.

The basic result from Experiment 3 was that the "correct" item was chosen more often in the Structured condition than in the Orthogonal condition (77% vs. 66% from Table 2). This finding supports the hypothesis that extracting a category's structure is facilitated by intercorrelated dimensions.

Table 2: The mean accuracy for humans and SUSTAIN in Billman and Knutson's (1996) Experiment 3.

	Orthogonal	Structured
Human	.66	.77
SUSTAIN	.60	.77

Table 3: SUSTAIN's best fitting parameters for the studies considered. SUSTAIN's parameters are not discussed in this paper, but this table is included for readers who wish to replicate our results.

function/adjusts	symbol	value
learning rate	η	0.0966
cluster competition	β	6.40
decision consistency	d	1.98
attentional focus	r	10.0
threshold	τ	0.5

Modeling Results SUSTAIN was trained in a manner analogous to how subjects were trained by using four randomly ordered learning blocks. No feedback was provided as all stimulus items were encoded as being members of the same category. New clusters were recruited according to the unsupervised notion of surprise. In order for SUSTAIN to mimic the forced choice nature of the test phase, a response probability was calculated for each of the two items. The ultimate response of the network was biased towards the item in the forced choice that had the strongest response probability.

SUSTAIN was run numerous times on both conditions in both experiments and the results were averaged. The best fitting parameters are shown in Table 3. SUSTAIN correctly predicts greater accuracy in the Structured condition than in the Orthogonal condition (see Table 2).

In Experiment 3, SUSTAIN's most common solution in the Orthogonal condition was to partition the studied items into three clusters. However, the nature of the three partitions varied across runs. SUSTAIN tended to focus on one of three correlations present in the Isolated condition and ignored the other two. For instance, during training SUSTAIN might create three clusters organized around the first two input dimensions (one cluster for each correlated value across the two dimensions) and ignore the correlation between the third and fourth dimensions and the fifth and sixth dimensions.

SUSTAIN also recruited three clusters in the Structured condition. The same dynamics that lead SUSTAIN to focus on only one correlation in the Orthogonal condition leads SUSTAIN to focus on all of the interrelated correlations in the Structured condition. When SUSTAIN learns one correlation in the
